ACADEMY OF SCIENCES.

Meeting of March 23rd, 1846, M. Mathieu in the Chair.

Digestion of Sugar and Starch, and Treatment of Diabetes Mellitus by the Exhibition of Alkalies.—Dr. Mialhe has on two occasions already directed the attention of the Academy towards this subject (see *Medical Times*, vol. xii pp. 40 and 184). At the meeting of March 23rd, M. Payen read the report of the commission appointed by the Institute to examine M. Mialhe's researches. Adopting the recently-received theory of the disaggregation of azotised substances in the digestive organs, Dr. Mialhe states that liquefaction results from the action of an acid on pepsin, a phenomenon which may be compared to the action of diastasis on amylaceous matter. Although it may be readily admitted that it is to the chemical influence of the special elements of the bile, that the assimilation of greasy substances is due, it is by no means so easy to account for the reactions by which saccharine and feculent food is rendered digestible. It is to the solution of the latter problem that Dr. M. has attached himself. Dr. M.'s researches on human saliva have led him to detect in its composition a principle presenting the closest analogy with diastasis, developed in plants, by the progress of vegetation, whenever amylaceous matter is to be dissolved, and carried in a liquid condition through the textures, for the purpose of new organic formations. Notwithstanding the extreme resemblance between diastasis and the substance detected in saliva by Dr. M., that gentleman hesitates in asserting the absolute identity of the two principles in the vegetable and animal kingdoms, and the commission cannot but applaud his reserve, because, in order to establish fully that still dubious fact, it would be necessary to compare the elementary composition of both products—an operation rendered extremely difficult by the apparent impossibility of obtaining perfectly pure substances which do not crystallise, and which are prone to become altered so long as they remain in a state of liquidity. A certain degree of doubt must still, therefore, hang over the solution of this question; but yet Dr. M.'s researches are fraught with interest, and lead to consequences of the highest order of physiological importance. Thus it can no longer be admitted that the elements of saliva do not singly act upon starch, but require to be blended together, in order to display their dissolving powers. Ptyalin, as hitherto prepared, had evidently been deprived of its most valuable properties,—and does not pre-exist in saliva, but is merely the altered animal diastasis, reduced to a state of inertness. Starting from the fact that the influence of alkalies gives to solutions of glucosis the power of reducing the binoxide of copper, the author conceives that the presence of alkalies is indispensable to the assimilation of sugar and starch, and attributes, therefore, diabetes mellitus, not to an undue production of saccharine matter, but to its non-assimilation. This new view of the disease, supported by ancient practical observations, points distinctly to the exhibition of alkalies or their carbonates, together with a highly animal diet, and strict abstinence from amylaceous nutriment, as the method most likely to be followed with success in the treatment of diabetes mellitus. The proximate cause of the disease is, in Dr. M.'s opinion, the absence of the alkaline principles from the blood; and several cases of marked improvement, and, indeed, of complete cure, are adduced in support of the alkaline medication. The commission does not, however, consider these cases to be sufficiently numerous to prove absolutely conclusive, and expresses a wish that Dr. M. should prosecute further his researches on this important subject.

Digestion compared in Carnivorous and Herbivorous Animals, by Dr. Bernard (de Villefranche).—The object of this memoir was to ascertain if the structural differences between the digestive apparatus of carnivorous and herbivorous animals are productive of any well-marked differences in the accomplishment of the functions of digestion and assimilation. The chyme, the chyle, and the urine, have been respectively examined; thus, in a large number of dogs, fed on animal diet exclusively, and sacrificed during the progress of digestion, the chyme in the small intestines was constantly found to be acid; the chyle opaque, homogeneous in consistency, and of a milk-white colour; and the urine transparent amber-coloured, and in a state of marked acidity. In rabbits, fed entirely on vegetables, the chyme was alkaline, the chyle transparent, and the urine clouded and alkaline. That these differences were not due to the special organisation of each class of animals, but to their diet, was clearly proved by another series of experiments. Two dogs and two rabbits, who presented in their urine the above-mentioned characters, were deprived of food for the space of thirty-six hours; at the expiration of that time, the urine, in all four, was clear, amber-coloured, and acid. The animal, during abstinence, living upon its own substance, is in the condition of those fed upon animal diet. In a third set of experiments, rabbits were nourished with animal—dogs with vegetable diet; after a few hours the urine of the former became acid, and the urine of the latter acquired alkaline properties. A constant connection seems, therefore, to exist between the state of the urine, chyme, and chyle, and the nature of the nutriment; and the mere examination of the urine with test-paper, leads to an accurate knowledge of the properties of the chyle and chyme. The following applications illustrate Dr. Bernard's theory:—A solution of cane-sugar is slowly injected into the veins of a dog; the urine remains clear and acid. But if a solution of grape sugar (*sucre de raisin*) be injected into the veins of an animal whose urine is transparent and acid, that fluid becomes speedily clouded and alkaline. The fact is accounted for by the ready assimilation of grape-sugar, and by the circumstance already known, that cane-sugar cannot be assimilated before having previously been submitted to the action of the stomach. Again, it is still admitted by some physiologists, that the section of the par vagum does not arrest the progress of digestion. Dr. B.'s experiments prove this opinion to be erroneous. Two rabbits, fasting for thirty-six hours, and presenting clear acid urine, were fed upon carrots; after two hours, their urine became clouded and alkaline; in one of them the par vagum was then divided; in a very short time, the urine of this animal returned to its acid character, and became transparent; whereas the urinal secretion remained alkaline and opaque in the other rabbit, on whom no operation had been performed.

Hemeralopia, by Dr. Magne.—Professor Arago communicated, on the part of Dr. Magne, the following case, which occasioned much hilarity. A man had presented himself to Dr. M., to be treated for night-blindness, an affection to which he had been subject ever since his birth, and which he referred to an ungratified wish of his mother while pregnant. In giving, very reluctantly, an account of Dr. M.'s case, Professor Arago seemed fearful of being, as in the case of the electric maid, taxed with credulity, and begged most distinctly to assert his disbelief in the existence of any such disease as hemeralopia. On being, however, assured by Professor Roux and Professor Velpeau, that hemeralopia and nyctalopia were forms of disease known for centuries, and on the existence of which no doubt could possibly be entertained, the learned secretary of the Institute observed that, at all events, physicians would not, perhaps, be disposed to admit the second part of Dr. Magne's communication, which appeared of so preposterous a nature, that he was almost ashamed to read it. "Is it a fact, that turkeys

are blind at night?" (Immense laughter.) The mother of the person whose case Dr. Magne brings forward, is stated to have had, during her pregnancy, an ungratified desire for a piece of turkey; and to this circumstance is attributed the disease of the child, who presents, as an aggravating coincidence, a large turkey-comb in one axilla. Prof. A. would only remark on hemeralopia, that if thereby is meant merely a diminution of the powers of vision, in a weak, crepuscular light, it is a fact so common as to be unworthy of attention; if, on the contrary, that term is applied to cases in which vision is perfect by day, and abolished by night, notwithstanding the use of artificial light, of sufficient strength, it is a phenomenon which can in no way be accounted for in the present state of the science of optics.

A NEW SIGN OF DEATH, by Dr. RIPAULT.—Dr. R. states that, when death is only apparent, lateral pressure on the eyeball does not change the shape of the pupil; but alters its circular form, by displacing the iris, when death is real.

The Meeting of the Institute of March 30th, was entirely consecrated to an uninteresting debate on railway accidents, or rather, on the expediency of calling to this subject the attention of government. No communications were read.

ACADEMY OF MEDICINE.

Meeting of March 31st, 1846, Dr. ROCHE in the Chair.

PARACENTESIS THORACIS IN ACUTE PLEURISY, by Professor TROUSSEAU.—M. Bricheteau made a favourable report on Professor Trousseau's former communication to the Academy on this subject (see *Medical Times*, vol. xii. p. 29).—M. Louis remarked that much reserve should be shown in recommending the operation: for his part, he had seen a very large number of cases of acute pleurisy; he never saw one which terminated fatally, or which would have warranted thoracentesis.—Dr Rouchoux stated that, although the cases to which the operation is applicable are very rare, still they exist: he recollected a patient who died in thirty-six hours of a double pleurisy with effusion. Post-mortem examination showed the lungs had preserved their elasticity, and that life might have been saved by the operation. Paracentesis thoracis, in Dr. Rouchoux' opinion, is more frequently indicated in acute than in chronic pleuritis; in the latter, the lung, compressed for a long space of time by accumulated fluid, loses, in a great measure, its powers of expansion, and the operation remains, to say the least, useless.—M. Honoré · The reporter has mentioned that, out of fifty-five patients operated on for empyema, fourteen died; this is an unusually large proportion.—M. Bricheteau having answered in a few words to the foregoing observations, the report was unanimously adopted.

MEMOIR ON THE VAGINO-VULVULAR GLAND AND THE VARIOUS ORGANS OF SECRETION, IN THE EXTERNAL (FEMALE) GENITAL ORGANS; by Dr. HUGUIER.—The vagino-vulvular gland, described by Bartholin and mentioned by several ancient writers, seems to have been entirely forgotten by modern anatomists. Its size is that of an almond; it is situated on each side at the union of the vagina and vulva, and opens by an excretory duct, seven or eight lines in length, in the groove which separates the labia from the hymen. This organ swells at the catamenial periods, and is more specially affected by sexual excitement; at all times where, in a healthy condition, the gland secretes a perfectly transparent fluid, any opacity of the secretion denotes disease. Its development always corresponds with that of the ovary of the same side, not only in the physiological but also in the pathological state —a circumstance which, if verified, would certainly prove invaluable to the diagnosis of ovarian disease. Dr. H. considers these glands as analogous in nature, functions, seat, and structure, to Cowper's glands in the male.

PARISIAN MEDICAL SOCIETY.

Meeting of April 1, 1846.

Dr. Watts having left Paris, Dr. Fleming, late president of the Royal Society of Edinburgh, was unanimously elected to fill the office of vice-president.

HOSPITAL OF LA CHARITE.

AORTIC ANEURISM COMMUNICATING WITH THE BRONCHI; by Prof. CRUVEILHIER.—J., aged sixty-three, was admitted into Prof. Cruveilhier's ward on February 1, 1846. He had been on four different occasions affected with acute pneumonia, and had suffered five months since from hæmoptysis, accompanied with deep-seated, dull pains in the left side of the chest, but he had been confined to his bed only six weeks before admission. Venesection and leeches having produced only temporary relief, he was brought to the hospital, where he died six days after. On being examined the day of his entrance, he presented the following symptoms:—Face pale and emaciated; pulse frequent, small, and irregular; tongue and lips dry and pale, and covered with a thick crust of coagulated blood. The thirst was intense, and the appetite was altogether destroyed; the bowels costive; considerable pain in the left side of thorax, extending from the breast to the false ribs. Expectoration of black coagulated blood mixed with viscid sputa; both sides of the chest were dull on percussion, posteriorly the dulness extending into the axillæ. In the right lung puerile respiration was manifest; in the left in front, mucous râle under the clavicle; posteriorly, vesicular murmurs so weak as to be almost inaudible, and dry crepitus at the lower parts. The sounds of the heart were natural, and the apex of the organ was very much deviated to the left.

Post-mortem Examination.—Pleural adhesions united both lungs to the walls of the chest; in the pericardium was found a small amount of serum; the heart was slightly hypertrophied, but its valves were healthy, and the principal anatomical alterations were found to occupy the arch of the aorta and the lung. From its origin to the arch inclusively, the aorta was gradually dilated, and the left and anterior wall of the artery was destroyed, and replaced by a brownish clot of blood of the size of a large egg, and formed of interwoven fibres, recalling by their disposition the internal aspect of the heart. This sanguineous plug was received in a cavity formed by the upper half of the inferior lobe, and a great portion of the superior left pulmonary lobe. When it was removed, several bronchi of minor size were found perforated, and partly closed by ancient and recent fibrinous deposits. The inferior part of the left lung was in a state of acute inflammation, and the bodies of the third and fourth dorsal vertebræ were worn and eroded by the tumour. The right lung was œdematous.

MILITARY HOSPITAL, GROS CAILLOU.

OSSIFICATION OF ARTERIES.—GANGRENE; by Dr. BROUSSAIS.—An old soldier, aged sixty-seven, was admitted, on the 17th of February, into Dr. Broussais' ward, complaining of headach and oppression; he was slightly relieved by immediate venesection; but, on being examined the next morning, pneumonia was detected in the right lung (dulness, crepitation, bronchial souffle, and bronchophony). Expectoration green and viscid. Venesection was repeated night and morning, and thirty leeches were applied to the chest. The blood was very fibrinous, and relief was experienced. Tartar emetic, eight and ten grains, were exhibited on the two following days, and the pneumonia seemed to be doing well, when heaviness and somnolency appeared; on the 26th of February a severe pain was complained of in the left leg, but no redness or swelling could be discovered. The next day a broad black stain appeared with phlyctenæ. The pulse was very small, at 100. Notwithstanding the exhibition of wine and stimulants, the gangrene extended, and in another day the left forearm became enormously distended, and death occurred on the 28th. On dissection, numerous ossifications were met with in the arteries of both inferior extremities, and in the brachial arteries. The popliteal nerve and left brachial plexus were in a state of violent inflammation, characterised by sanguineous injection of the neurilemma of the cellular structures, and also by circumscribed redness of the nervous filaments.

HOSPITAL NECKER.

EXTRACTION OF THE EYE-BALL.—CURE; by Dr. LENOIR.—A girl, aged nineteen, of a lymphatic temperament, was admitted under M. Lenoir's care on the 10th of January, 1846; she referred her disease to a fall which occurred in 1830, in which her face was wounded, and which left on the cornea of each eye stains still perceptible. In 1837 she consulted Prof. Sanson for her eyes, and the diagnosis which that surgeon wrote on his prescription was, blepharo-conjunctivitis on both sides, with albugo and pseudo-cataract of the right eye; both eyes were at the time cauterised every second or third day, and from that period forward the right eye has gradually increased in size. At the period of admission her eyes were in the following condition:—On the right side chronic inflammation of the follicles of the lashes; the eye-ball is evidently larger than the other, and the increase of size seems more particularly to bear upon its anterior half. The lids can still, however, by a slight effort, be made to cover the entire surface of the eye. The conjunctiva is very much injected; a circle, of a bluish colour, extends about two lines in breadth all round the cornea, which presents several stains. The iris is very much dilated, and insensible to light, although it is occasionally the seat of a sort of tremulous movement. In the posterior chamber could be seen a whitish substance presenting the aspect of cancer of the retina. Vision was completely abolished. In the left eye, with the exception of some slight nebulæ, vision was perfect. Believing in the existence of malignant disease, M. Lenoir was easily induced to remove the eye, useless as an organ of vision, and constituting a deformity by its size. The operation was performed according to the method recommended by Bonnet (of Lyons). That surgeon has carefully described a fibrous capsule, wherein the posterior part of the eye-ball is received very much in the same manner as the acorn in its cupula. This aponeurosis, called by Cruveilhier "orbito-ocular aponeurosis," is concave anteriorly, and inserted around the anterior extremity of the optic nerve with the neurilemma of which it seems continuous, and surrounds, without any intimate adhesion, the two posterior thirds of the eye-ball. Its anterior attachments are double, the fibrous lap dividing into two fasciæ; the thickest and most anterior of which is inserted to the edge of the tarsal cartilages, the other terminating around the cornea, underneath the conjunctiva. This aponeurosis isolates the eye-ball from the fat, the arteries, veins, and nerves of the orbit, and furnishes fibrous investments to the muscles; and on its disposition M. Bonnet has founded a new operation for the extraction of the globe of the eye. It was this method M. Lenoir employed in the present case. The ocular conjunctiva was first raised at one line inside the cornea, and incised with a pair of curved scissors, which were afterwards carried round the cornea so as to divide the conjunctiva completely. The six muscles of the eye were then divided; and the scissors were carried along the external face of the eye-ball, and the optic nerve was cut close to the sclerotic membrane, in front of the posterior insertion of the aponeurosis. Very little pain was experienced during the operation, and not half an ounce of blood escaped. The wound was dressed with cold water. On dissection of the eye-ball, the sclerotic membrane was found very much thinned in several parts; the crystalline lens was opaque, and partly absorbed; it was the remains of the lens in the posterior chamber which had been taken for a malignant growth. The patient did well, and left the hospital cured on the 14th of February.

TREATMENT OF DIABETES MELLITUS BY BALSAM OF PERU.—The *Journal des Connaissances Medico-Chirurgicales* reports a fact of great importance, if experience will confirm it.

A man, forty years of age, of cachectic constitution, presented all the symptoms of diabetes. Dr. Vanhes prescribed immediately forty to fifty

drops of balsam of Peru, to be taken three or four times a-day, and recommended him to save his urine.

At the end of a week's treatment, the patient, who perceived his condition already ameliorated, brought his urine to the author. On evaporation, this urine furnished a residue having the odour, consistence, and appearance of honey. Combustion disengaged the smell of caramel. The urine of the patient, kept for several days, became acid. whilst natural urine becomes ammoniacal.

The diagnosis thus confirmed: Dr. Vanhes raised the dose of balsam Peru to four or five teaspoonfuls daily; the result surpassed his expectations. After three weeks treatment, the thirst had disappeared, and the patient passed urine once only in the night. At the end of five weeks, the urine having taken its normal characters, and the patient being entirely re-established, the balsam of Peru was discontinued.

DAN. MACARTHY, D.M.P.

Germany.

(From our own Correspondent at Vienna.)

ON THE LAWS OF THE FORMATION OF THE SPERMATIC FILAMENTS; by Professor KÖLLIKER. — The recent investigations of this author have conducted him to results, thus far of great importance, that they lead to general laws, which are valid in regard to all animals. The author has enunciated these results as follows:—I. The element out of which the spermatic filaments are formed consists of simple nucleated cells or organs, which originate from the transformations of a single cell. The principal varieties of this element are: 1. Large cells, with numerous nuclei; these are found in the mammalia, in birds, fishes, amphibia, plagiostoma, arachnida, cephalopoda. 2. Parent cells, with numerous mononucleated filial cells, are found in locustiva, coleoptera, libellulida, radiata, and partly in polypi. 3. Aggregations of mononucleated cells, with a naked central mass connecting them together, characterise many of the annelides, and probably all the gasteropoda. 4. Aggregations of mononucleated cells, without the central connecting mass, are found in amphioxus, musca, partly in annelides, trematoda, conchae, echinorhynchus, planaria, and nemertes. (?) II. The spermatic filaments are formed endogenously, probably always, in the nuclei of the above-mentioned cells, and one spermatic filament in one nucleus. The filaments originate from the deposition of the (fluid?) contents of the nucleus upon its membrane, and, perhaps in all cases, grow independently till they reach their final form and magnitude. III. The spermatic filaments are freed by the dissolution of their parent cells and nuclei, and are often found, even in cells, united together in bundles.—*Froriep's New Notices*, No. 789

ON THE EFFECT OF BLOOD-LETTING ON ANIMAL HEAT; BY PROFESSOR H. NASSE.—This writer has made numerous experiments on dogs, rabbits, and goats. Five or seven hours after feeding them he abstracted six or eight ounces of blood, and during the time which elapsed, from five minutes to four hours, after the venesection, he exactly determined their animal heat by means of a thermometer introduced into the vagina and intestinum rectum. He found that the diminution of the blood, and its necessary consequence, diminution of the blood-corpuscles, was by no means followed by a decrease, but by an increase of the animal heat. Nasse explains this phenomenon in the following manner:—1. The functions of respiration and circulation are much accelerated after bleeding. 2. The power of absorption possessed by the vessels is increased; the fat deposited in the cellular tissue by this means reaches the blood, where it is used as the most available fuel. 3. All the watery secretions are at once lessened by bleeding; in this way less heat is lost. It is evident this observation of Nasse's directly contradicts the law laid down by Prévost and Dumas, that the heat of animals is in direct proportion to the number of their blood corpuscles, because if, in the same animal, the heat can increase with the diminution of the blood corpuscles, only when circulation and respiration become accelerated; it is scarcely credible that, in different species of animals, where the number of pulsations and respirations so greatly varies, the quantity of the blood corpuscles should be the only circumstance affecting the heat. When the animal classes of fishes, reptiles, birds, and mammalia are compared with each other, this law obtains, in a general sense, though, in comparing birds with mammalia, numerous exceptions are found. Nasse has often observed a greater degree of heat in geese, turkeys, and hens than in mammalia, though the number of blood corpuscles is not greater in the former than in the latter. If the mammalia be compared with each other, we find the greatest contradictions, though, by this means, the law should be clearly established, since these animals, similar in conformation, differ in the number of blood corpuscles, and in the grade of animal heat. As regards heat, the domestic animals stand in the following succession:—swine, goats, rabbits, dogs, and horses; arranged according to the number of blood corpuscles:—swine, dogs, horses, rabbits, goats. That the number of pulsations does not compensate this difference is proved by the fact that, in the dog, the number of pulsations surpasses that of the goat by twenty beats, and yet the former has always a greater number of blood corpuscles, and a less degree of heat, than in the latter. Finally, as are also the latest researches of Roger, the pathological fact that, in man (according to Andral), the animal heat remains always the same, even during the greatest poverty, in respect of blood corpuscles, is unfavourable to the universal validity of Prévost and Dumas.—*Med. Corr. of the Rhenish and Westpl. Physicians, 15th Nov.*, 1845.

ANALYSIS OF CONCRETIONS OF THE LUNGS; BY BARON GORUP BESANEZ, M.D.—This investigation has a double interest for our readers, because, in the first place, Dr. Wright's masterly essay on this subject (*Medical Times*, Nov. 15, 1845) does not contain a similar case, and because his enunciation, "concretions are chiefly found in the lungs of consumptive patients, and others whose lungs are the seat of chronic morbid lesion," is somewhat qualified by the observations of Gorup-Besanez. A man, aged forty-five, strong and muscular, fell down a stair when drunk, and died from fracture of the skull. Dissection showed nothing abnormal, except the injury of the cranium. In the lungs, however, a coral-like ossification was found in the parenchyma, in the course of the smaller bronchial ramifications. This concretion was as thick as a crow quill, ramified through the whole length and breadth of the lungs, and, when taken out, broke with a crack. For the rest, the lungs were free from tubercles, cicatrisations, or hepatisations, freely admitted air and blood, and the man had been subjected to hard labour as a bricklayer's assistant, without ever complaining of annoyance from asthma. The fragments had quite the form of bronchial ramifications—were hard, but not heavy—transparent, and greyish yellow. Their chemical composition was as follows:

Fatty matters and traces of soluble salts	17·17
Mucus	32·46
Phosphate and carbonate of lime, with traces of oxide of iron	50·37
	100·00

—*Heller's Archive of Physiol and Pathol., Chem. and Microscopy*, p 16, Feb. 1846

ON THE EXTRACTIVE MATTERS OF THE URINE; BY PROFESSOR SCHERER.—Under this name a mixture of substances was long understood, which, after a separation of the more characteristic urinary constituents—viz., of the urea, uric acid, and saline matters, was obtained as a body partly soluble in water, partly in alcohol. This body was obviously a compound of substances partly organic, partly inorganic. Scherer has made the colouring matter of the urine—which, after a preliminary inquiry, seemed to be the chief ingredient of these extractive substances—the subject of further investigation. In order to obtain this material as nearly as possible in the form in which it exists in the urine, he proceeded in the following manner:—1. Urine, recently evacuated, was treated with a solution of nitrate of barytes to get rid of the sulphuric, phosphoric, uric, and sometimes also of the carbonic, acids. The precipitate, separated by filtration, consisted of a compound of barytes with the above acids, and also contained mucus of the bladder and colouring matter of the bile, when the urine contained any of the latter. In the latter case the colour of the precipitate would be green or pale blue, according to the quantity of the colouring matter. When the precipitate was subjected to heat and treated with hydrochloric acid and alcohol, distinct traces of the colouring matter of the bile were found in the urine, even of healthy individuals, especially in summer. By evaporating the alcohol, and washing the residuum with water, the colouring matter may be obtained in a solid state. 2. The filtered solution was treated with a neutral one of acetate of lead, until no further precipitate was formed. The precipitate obtained was then filtered and washed. It appeared highly coloured, and, besides chloride of lead, contained the greatest quantity of the extractive colouring matter. The precipitate was now treated with hydrochloric acid and alcohol During this operation the alcohol takes a red or dark brown colour, according to the nature of the colouring matter and the concentration of the solution, and can now be easily separated by *cold* filtration from the newly formed and obviously present chloride of lead, which is insoluble in alcohol. If the alcoholic solution be now evaporated as quickly as possible in flat vessels in a water-bath, a heavy substance, of a dark-brown or black colour, will remain, from which the remaining traces of muriatic acid can be removed by washing with cold distilled water. By drying, the black mass becomes pulverisable. The powder obtained contains scarcely a perceptible trace of incombustible residuum. It is almost insoluble in cold—somewhat more so in warm—water; easily soluble in free alkalies and their carbonates; also in alcohol—viz., when a free acid is present; but not so easily in alcohol with free alkalies and their carbonates. It burns with a peculiar smell, which is very different from that of burning urine, and more resembles that of humin, with which substance it has a great likeness. 3 The filtered fluid, which was still slightly coloured, was now treated with basic acetate of lead, and by this means a precipitate was again obtained, abundant, but less coloured. This was also filtered and washed. If this precipitate be treated in the same manner as the former one, a coloured powder is also obtained, but in a smaller quantity, and of a brighter hue 4. The filtered fluid was now quite colourless, it contained urea and the residuary salts of barytes and lead. If these salts be removed by means of sulphuric acid, the fluid, by concentration and with a disengagement of acetic acid, yields a yellowish syrup-like mass, from which a part of the urea will come out as a nitrate by crystallisation; the greater part, however, will be changed into ammonia. Lactic acid is not to be discovered in this fluid. While Scherer in this manner obtained the colouring matter of the urine from the secretions of several healthy and unhealthy individuals, and made repeated elementary analyses with it, he arrived at a number of important results. Thus, he found that the part of this colouring matter richest in carbon and hydrogen was precipitated by neutral acetate of lead; the part poorest in these elements by basic acetate of lead, which is also the cause that the precipitate obtained by the neutral salt has a deeper colour than that obtained from the reaction of the basic salt. Further, it appears that, in general, the quantity of colouring matter obtained from precipitation with the neutral salt is less in those cases where the colouring matter is highly oxidised than where it exists in a lower grade of oxidation. Where a portion of the colouring matter exists in a very slightly oxidised state, it is extremely easy to obtain the part most slightly oxidised, by bringing the urine to the boiling point and then mixing it with concentrated hydrochloric acid. All urine so treated becomes dark-coloured, and when it contains slightly oxidised colouring matter, during cooling it deposits—besides crystalline uric acid—a considerable quantity of this colouring matter as a fine powder, of a dark brown, often even bluish, colour. This sediment is easily soluble in alcohol, and, therefore, can be obtained free from uric acid. In this manner it can be easily ascertained whether the colouring matter of urine, in a pathological state, contains more or less carbon. The darker the urine becomes during a short boiling in a test-tube with hydrochloric acid, and the more dark brown colouring matter it deposits during cooling, the richer it is in this colouring matter, and the latter

contains a proportionately large quantity of carbon. During a long exposure to the air, this colouring matter gradually oxidises, like that of the bile, and in exchange loses in carbon and hydrogen. It is remarkable, in a chemical point of view, that Scherer obtained 18·2 per cent. of sulphate of ammonia, or 3·91 per cent. of nitrogen from treating the extractive colouring matter with sulphuric acid; while Heintz and Ragsky in their quantitative determination of the urea by means of concentrated sulphuric acid, have considered the ammonia arising from the extractive matters, and, therefore, the nitrogen, as existing either in an extremely small quantity, or not at all. The result of his researches affecting pathology and physiology have been summed up by Scherer as follows:—1. The greater portion of that matter, hitherto designated by the name of extractive matter, is a peculiar substance analogous to the animal colouring matters. Hence Scherer calls it the *colouring matter of the urine*. 2. As its elementary composition varies with the varying state of the individual, it differs in this respect from urea, uric acid, &c., the component elementary principles of which always maintain a certain proportion in regard to each other. 3. In regard to elementary composition, this colouring matter is distinguished from the colouring matter of the bile (which probably originates from the venous blood) by containing less carbon and hydrogen. 4. It is probable that both colouring matters, that of the bile as well as that of the urine, are formed from the hematin of the blood, whilst the other matters also existing in the above fluids may possibly arise from the so-called protein compounds of the blood and organic tissues. This will be clearer when these three colouring matters are placed in juxtaposition:—

	Hematin (Mulder.)		Colouring matter of the bile (Scherer.)		Ditto of the urine. (Scherer.)
Carbon...	70·19	......	68·19	......	58·43
Hydrogen	5·76	......	7·17	......	5·16
Nitrogen	11·16	...	7·07	....	8·83
Oxygen	12·59	...	17·26	....	27·58

5. Because the colouring matter of the urine does not always preserve the same proportion in its composition, it is, therefore, clear that it, and the matter out of which it is formed by the vital process, exist in a perennial metamorphosis, and indeed in a metamorphosis which appears to be chiefly that of oxidation or decay. 6. This oxidation affects both the carbon and hydrogen, for the latter is also found in different quantities. 7. During a continued and plentiful use of food rich in carbon—*e. g.*, of fat—the colouring matter of the urine—*ceteris paribus*—appears to leave the body in a somewhat less oxidised state. 8. The greater the consumption in a given time of organic tissues by the vital action of the organism, without a proportionately increased activity of the pulmonary and hepatic functions, the less intensively does the process of decarbonisation take place, though, perhaps, it is more extensive. 9. During the formation of the colouring matter of the urine, relations seem to exist similar to those obtaining during the formation of urea and uric acid. Here, also, we find a more highly carbonised uric acid, co-existing with an increased metamorphosis and an augmented waste of organic matter, when the pulmonary and hepatic functions do not increase in a similar proportion—*i. e.*, when the intensity does not keep pace with the extension of their action. The close analogy with the formation of uric acid may also be concluded from the fact, that in general urine rich in uric acid contains a colouring matter abounding in carbon and hydrogen.—*Wohler and Liebig Ann.*

On the Presence of Copper in the Bile and its Concretions. By Bertozzi, Heller, and Baron Gorup Besanez, M.D.—Bertozzi incinerated the organic substance of the bilious concretions, dissolved the ashes remaining in very diluted hydrochloric acid, filtered the solution, then acidulated it slightly, and passed a current of sulphuretted hydrogen gas through it. In this way he generally obtained a precipitate in dark brown flakes. He now separated the precipitate from the fluid and dissolved it in nitric acid, or in aqua regia. To drive off the excess of acid he evaporated the solution, and again dissolved the dry residuum in distilled water. The solution was now treated with ammonia, in excess, and a scarcely perceptible blue tint was sometimes the result; but when a drop of ferrocyanide of potassium was added, a reddish-brown precipitate was invariably obtained. From fourteen gall-stones which the Milanese chemist analysed in this way, he found that the richer the concretion in the colouring matter of the bile the more evident was the re-action for copper; but in completely white concretions he could find no copper whatever. Bertozzi is of opinion that the copper is derived partly from the food, and partly from copper cooking-vessels, and deposits itself in the liver, like quicksilver, arsenic, and other metallic poisons. From the facts, however, that he could never find copper in the bile itself—that the copper is always accompanied by the colouring matter of the bile—and that the nucleus of the bilious concretions is almost always, more or less, of a yellow colour—Bertozzi holds himself justified in supposing that the presence of copper in the gall-bladder is often the cause of the formation of the nucleus, and that the supply of copper in the organism has, therefore, a connection with the formation of bilious concretions. Heller repeated the experiments, and also confirms the truth of the observation that the coloured gall-stones contain much copper. He recommends a much more simple mode of investigation. By his method the stone is ground to a coarse powder, incinerated in a platina crucible, dissolved in water, acidulated with nitric acid, and the solution is then neutralised. The known reagents will show the presence of copper in this solution. Heller and Baron Gorup-Besanez have lately shown the existence of copper likewise in the bile; the former in the human bile, the latter in that of cattle. Heller is of opinion that, even when the presence of copper is rendered doubtful by extended reaction, its existence is certain when the fixed salts, melted in the platina crucible, take, in cooling, a light blue or blueish-green colour.—*Heller's Archives for Physiol. and Pathol. Chem. and Microscopy.*

On the Flesh of Man and other Vertebrata. By Baron Bibra, M.D.—Singularly enough, Bibra was the first who subjected somewhat of human flesh to chemical investigation. We can, however, give here only a very short report of his analyses, which extend over numerous classes of animals. We shall confine ourselves to the final results at which Bibra has arrived, and we shall first give the qualitative, then the quantitative results. The *fibrin* and *albumen* of the muscular tissue is indentical, in a chemical point of view, with those substances in the blood, bearing the same names, and, treated in like manner, they yield protein. The fibrin and albumen of the flesh always contain phosphate of lime and also phosphate of magnesia, which salts appear (as the gelatine of the bones) to belong to the protein compound itself. From the *gelatine* the quantity of cellular tissue in flesh can only be estimated approximatively, as the muscular fibre is also turned into a gelatinous substance by continued boiling. In general the formation of gelatine takes place under quite peculiar circumstances. Thus, in investigating bones, Bibra found that, after removing the earthy parts of the bones, and washing the cartilaginous substance with water, the cartilaginous substance assumed all the peculiarities of gelatine, in many fossil bones without previous boiling, and after boiling for four hours in those bones which had lain for some time in a peat bog. He says the *extractive matters* are compounds of protein, which partly seemed about to undergo those transformations necessary to form cellular tissue, arterial membrane, muscular fibre, &c., out of protein; partly also consisted of waste material, which, useless in the functions of life, would be thrown out of the system as soon as possible. The similarity which Berzelius discovered between one of these matters and an extractive matter of the urine, is in favour of this opinion. Accordingly, the whole mass of extractive matters in the muscular fibre is in a state of continuous transformation; from which it follows, *à priori*, that the mutual quantitative proportions of these matters must be extremely variable, according to the lessened or increased metamorphosis of the tissues, and that many of them will be different in different animals. Relative to *fatty matter* it is worthy of remark, that although Bibra, before drying the flesh, always removed the fat visible to the naked eye, he often found a considerable quantity of fat in dried flesh. From this, and from the fact that even in the flesh of animals starved to death, some fat is always found, he concludes that a certain quantity of fat is an essential constituent of muscle. Further, Bibra relates respecting a human body cast on shore at high-water, that he found the greater part of it changed into fat (Fourcroy's adipocire), and he holds for certain that a similar change takes place underground, particularly when the air is excluded. Bibra leaves the question undecided, as to whether *lactic acid* exists in flesh. In the fluid of quite recent flesh still retaining the animal heat, he has often found no traces of acid, and sometimes weak, but never strong traces. Almost always the latter was the case when the flesh had lain for some time. From this it appears that a free acid is sometimes present in muscular flesh; Bibra, however, does not know if it be lactic acid, and as little if the acid of fresh flesh be identical with that of flesh kept for some time. The tribasic phosphate of soda forms the chief constituent part of the *ashes*; the chloride of natrium is present in a small, often merely perceptible, quantity, so that it exists in a much larger quantity in ashes of the blood than in flesh. He often found sulphuric and carbonic acids in the salts soluble in water. The alkalies were, invariably for the most part, soda, and a little potash. The salts insoluble in water were phosphates of lime and magnesia; the first preponderated, with a little oxide of iron; sulphate of lime was seldom present. Regarding the phosphates of lime and soda, Bibra is of opinion that, at least in warm-blooded animals, they may be considered as integral organic constituents of the flesh, and the phosphate of soda belongs to the fluids, the phosphate of lime to the muscular fibre. Potash and magnesia are present by substitution. In the case of one and the same individual, Bibra could not discover a determinate reciprocal relationship between the ashes of the blood and of the muscle. We now come to the quantitative results, and we shall first state the numerical composition of *human flesh* as it was obtained from two analyses of the muscul. pect. mag. The first analysis is of the flesh of a man who died of suppuration of a joint; the second of that of a woman who drowned herself, but remained in the water only about a quarter of an hour.

	First.	Second.
Muscular fibre, vessels, nerves ...	16·83	15·54
Cellular tissue changed into gelatine	1·92	2·07
Albumen soluble .... Colouring matter	1·75	1·93
Watery extract with salts ...... Alcoholic extract with salts	2·80	3·71
Fatty matter		2·30
Water		71·45
	100·	100·

In the first subject the ashes weighed, 4·39 per cent.; in the second, 4·480 per cent.; and their composition was as follows:—

	First.	Second.
Alkaline phosphates .... Carbonate of soda	72·95	63·58
Earthy phosphates .... Oxide of iron	15·03	21·12
Chloride of natrium	10·30	13·44
Sulphate of soda	1·72	1·86
	100·	100·

In the *mammalia*, the quantity of water is always from 77 to 78 per cent.; on an average the albumen amounts to 20 per cent.; gelatine to almost as much; muscular fibre to 15 per cent; the quantity of extractive matters is more variable, viz., younger individuals possess less of it than older ones. In the dried flesh of different animals, the residual salts were generally present in much the same quantity, *i. e.*, 5 per cent. Of the different salts, the earthy phosphates appear to preponderate over the alkaline substances in the carnivora. Old *birds* have somewhat less water in their flesh than mammalia, but the same quantity of muscular fibre; young birds have much less muscular fibre. In old birds the quantity of albumen is similar to that of the mammalia, or even greater, and the extractive matters are always present in a larger quantity. In the *reptilia*, the quantity of muscular fibre is less than

in warm-blooded animals; in rana the colouring matter is scanty; coluber has more of it. In *fishes*, the quantity of water is like that of reptiles, and surpasses the quantum of warm-blooded animals, also the quantity of muscular fibre in their flesh is proportionably small. From forty-six investigations, relative to the quantity of fat in the muscle of mammalia and birds, Bibra concludes that in youth the quantity of fat increases by plentiful feeding; in old age it decreases. Carnivora living in a wild state, mammalia, and birds have as much fat as well-fed herbivora. Aquatic birds appear to have more fat than other orders. In conclusion, Bibra communicates some analyses of *pathological formations*. In general they yield like healthy flesh—a protein compound, extractive matters, fat, gelatine, and sometimes even chondrin; also Bibra never found in them any salts save those existing in flesh, but the quantity of the salts was often much greater. Thus, in a fibroid of the under jaw, he found a quantity of salts amounting to 8·33 per cent. (neither chloride of natrium nor iron); in cancer of the præputium, 10·80 per cent.; in cancer of the female breast, 9·30 per cent; in fungus medullaris of the eye, 12·5 per cent. They also contain generally more fat than in healthy flesh. In the fatty tumours, Bibra found that the fat generally consisted of oleine; with the microscope there could not be discovered crystals of cholesterine, and it generally gave no ashes, so that the small quantum of ashes yielded by these tumours originated from the membranous substance remaining from the treatment with ether. This last yields by boiling much gelatine, which is not free from chondrin If this substance is dried in a water bath, and then heated with water, it shows very few traces of extractive matters.—*Roser and Wunderlich, Med. Quarterly Journ.*

Spain.

The following "*Anatomico-Pathological Observations upon Phthisis*," the production of D. José Seco Baldor, a physician attached to the Military Hospitals of Madrid, have been translated from one of the latest numbers of the "*Boletin de Medicina*" in our possession. We regard them as peculiarly valuable and interesting; not only for the pathological facts contained in them, but for the satisfactory views which they exhibit, of the present state of opinion and practice, among the physicians of Spain, on the important subject to which the memoir relates. For the correctness of these opinions, we, of course, do not hold ourselves responsible. We deem it best to give them, without note or comment, to our numerous readers.—P.

Modern writers generally agree in attributing pulmonary phthisis to the development of tubercles in the lungs. Yet some, whose opinion on the subject is entitled to great respect, regard the disease as essentially consisting in chronic inflammation of the organ, and not dependent upon tubercles; which do not invariably exist; and which, when existing, constitute not, in their view, the principal source of the symptoms. An equal diversity of opinion prevails on the origin and nature of tubercle, and its connection with the lesions of the respiratory organs.

To supply data for the solution of these questions, is the principal object of the present memoir. And, although the cases, which it exhibits, are few, the important circumstances, wherein they all concur, may render them useful and interesting to the pathological anatomist.

No one, in the present day, will venture to deny the advantages of auscultation in the diagnosis of thoracic diseases. Yet the value of the stethoscope is not appreciated as it deserves. In Spain, the instrument is very little used, or wholly neglected The following cases, particularly the first and second, are calculated, in the author's view, to inspire greater confidence, among his countrymen, in stethoscopic signs. The six following cases prove that pleurisy may give rise to the formation of tubercles in the pleura, the pseudo-membranes, and parenchyma of the lungs. In the 9th and 10th, the tuberculization obviously resulted from parenchymatous—in the 11th and 12th, from catarrhal, inflammation of the lung. The 13th is a case of hæmoptysis in a subject of phthisical constitution, without the existence of one solitary tubercle in the pulmonary structure; and proves that this hæmorrhage may precede the formation of tubercle; although commonly succeeding it; as in case 14th, and analogous cases, of daily occurrence.

Case 15th affords an example of the development of tubercles in one organ previously inflamed, and, at the same time, in another which had not been attacked by inflammation. In cases 16th and 17th, the inflammation, as almost always happens, had not been antecedent, but consecutive. The 18th is a singular case of tubercular diathesis. In this, tubercles were discovered, not only in the parenchymatous structure of several organs, but also in the blood which had been drawn from the patient.

Lastly, the 19th is a case in which the patient, after having exhibited all the characteristic signs of phthisis, perfectly and most unexpectedly recovered. Here, however, the existence of tubercles may be doubted. It is probable that the cavern, discovered in the left lung was the result of common, not of tuberculous suppuration.

On the whole, it may be inferred from these cases, 1. That tuberculization is frequently preceded by inflammation, as the occasional cause, of the part in which the tubercles are developed: 2. That tubercles, once developed, operate, after a time, as extraneous bodies, and either excite consecutive inflammation, or aggravate that already existing: 3. That the general tubercular diathesis apparently consists in a peculiar state of the blood, sufficient, of itself, for the formation of tubercles in the various organs, independently of irritation of any grade or species: 4. That phthisis is curable: and 5. That all the characteristic symptoms of this disease may occasionally be developed, without the existence of tubercles in the lungs. At the same time, these cases may serve to illustrate some important points in pathological anatomy and semeiotics.

CASE 1.—*Chronic Pleuro-pneumonia; Pulmonary Tubercles; Caverns opening into the left Cavity of the Thorax; Mucous and Cavernous Râle; Amphoric Sound.*

A man, of weakly constitution, aged twenty-one, was, at the close of April, 1836, admitted into the Military Hospital of Lavapies. The various gastric symptoms, of which he complained, were attributed, by him, to the repugnance with which he invariably ate his mess; and disappeared after a few days' residence in the hospital. He had, moreover, dyspnœa, frequent cough, muco-purulent expectoration, and fever. There was no hæmoptysis; but slight and wandering pains in the breast. He was pale, emaciated, and feeble.

May 8th.—The following symptoms were found upon minute examination, cough frequent and troublesome; expectoration difficult, scanty, consisting of a muco-purulent, thick fluid, for the most part, of a yellowish-white colour, but mixed with some portions of a pinkish-grey, and sanious; dyspnœa considerable; reclination supine; wandering pains in the whole chest; respiration sibilous over all the right side of this cavity, mucous in both lateral regions, but more so in the left than in the right, and in the posterior regions of each side, than in the others The respiratory murmur more or less obscured by râle, and, in some points, extinct. The sound of the thoracic parietes dull in the whole of the left side, except the anterior superior portion, and more so in the inferior regions than in the others; diminished, but not wholly dull, on the right side. The skin hot, dry, and earthy. Pulse very quick and small; night-perspirations, especially from the middle of the body, upwards. Sleep interrupted by cough. Appetite impaired. thirst natural. Emaciation: extreme debility

From 8th to 16th.—State of the patient daily worse. Mucous *râle* audible at a considerable distance, and evidently cavernous. Every evening, an access of fever, followed by more profuse night-sweats.

16th.—In addition to the *râle*, distinct amphoric sound in the left posterior and lateral regions.

17th and 18th.—This sound equally audible, especially on coughing. Dyspnœa extreme: expectoration well-nigh suppressed. Death on the 19th of May.

NECROTOMY TWELVE HOURS AFTER DEATH.

Thorax.—Left cavity containing a pint of purulent serum. Corresponding lung strongly adherent to the ribs, pericardium and diaphragm, by cellulo-fibrous bands and false membranes. The adhesion to the diaphragm was merely by the anterior and posterior extremities of the base of the lung; which, however, adhered to the ribs in its whole external surface and the adhesion formed an oblique line from the posterior part of the vertex to the anterior of the base. The fluid, occupying principally the inferior part of the cavity, passed to the superior, behind the lung. The costal and diaphragmatic pleura was red, thickened, indurated, opaque, and, in many places, covered with thick and membraniform pus. Pulmonary pleura thickened, opaque, indurated, whitish, and fibrous, but less so in the middle third of its anterior portion than elsewhere. All the parenchyma of the lung, except the anterior border of the superior lobe, condensed, and full of tubercles and caverns, especially at the posterior part. In the centre of the superior lobe, near its posterior border, two orifices, of the diameter of a writing-quill: in these, some of the bronchial tubes and caverns terminated, and, through them, communicated with the cavity of the pleura. The right lung adherent to the ribs and pericardium; but unattached at the base: the lobes adhering together; and their parenchyma condensed, but in a smaller degree and extent than the left; and the tubercles and caverns less numerous than in that. The costal pleura red in its posterior portion: the pulmonary, fibrous in divers points, and of a red and whitish colour The caverns, in both lungs, filled with a muco-purulent matter in some instances, it was sanious, or composed of pus and blood. In the pericardium, a quantity of transparent yellow serum. Heart small.

Abdomen.—Peritoneum opaque, whitish, and full of serum resembling that of the pericardium. The omenta converted into a cellulo-fibrous membrane, and perfectly destitute of their peculiar adipose appearance. Stomach adherent to the colon, spleen, liver, and diaphragm. The whole mucous membrane of a pink colour.

REFLECTION

On the admission of this patient into the hospital, he presented various symptoms of gastric irritation. But the principal cause of the fever and emaciation evidently resided in the thorax. The exploration, of the 8th of May, shewed, beyond a doubt, that the man was in the last stage of tubercular phthisis, complicated with chronic inflammation of the pleuræ, of the parenchymatous structure of the lungs, and the bronchial mucous membrane.

On the 16th, was discovered, in the left side, the amphoric sound—*Bourdonnement amphorique de Laennec*—and this sign was clearly diagnostic of the existence of one or more caverns opening into the cavity of the pleura, and of the penetration of the atmospheric air to the purulent fluid which it contained. Thus were the opinions founded, during life, on the results of percussion and auscultation, admirably verified by dissection. In fact, both pleuræ, and more particularly the left, exhibited unequivocal vestiges of chronic inflammation; and the effusion of pus satisfactorily accounted for the obtuse sound of the greater portion of the left side, the absence of the respiratory murmur, and, above all, the amphoric sound Lastly, the parenchymatous inflammation, which, doubtless, contributed to the diminution, or absence, of the respiratory murmur, and of the normal sound of the thoracic parietes, was, also, discovered.

This case suffices, of itself, to demonstrate the value of percussion and auscultation in the diagnosis of the various lesions of the respiratory organs; and to prove that, by them only, can be detected the existence of certain lesions, as, for instance, the penetration of caverns into the pleura, and the consequent introduction of atmospheric air into its cavity This assertion is not advanced with the view of depreciating the value of other diagnostic signs; without the aid of which percussion and auscultation will be almost always insufficient

According to Laennec, the thickening of the pleura, when inflamed, is not real but apparent, and owing to the formation of several layers of false membrane, which adhere together, and are still capable of being separated by cautious dissection.

That this takes place in many instances, cannot be denied; but, in the present case, and in many others which might be cited, such separation was absolutely impossible; for the pleura was permanently thickened and converted, like the peritoneum and omenta, into a fibrous membrane. It seems strange that Laennec, while admitting the fact of the transformation of the various textures, one into the other, either by the normal progress of organization, or in consequence of alterations in the process of nutrition, admits not the possibility that an inflamed serous may pass into the class of fibrous or other membranes. Nothing, moreover, tends to prove that the pseudo membranous layers adhere so intimately together, and to the pleura, as to constitute one single membrane, of the fibrous or other class.

CASE 2.—*Chronic Pleuro-pneumony of both Sides; Pulmonary Caverns opening into the left Pleura; Mucous and Cavernous Râle; Amphoric Sound.*

On the 1st of June, 1836, a man was admitted into the Military Hospital of Lavapies. He had been ill, from his own report, two months, but apparently, much longer. He was pallid, emaciated, and very feeble. He had considerable fever, great difficulty of inspiration, frequent cough, with muco-purulent expectoration, extreme sensibility of the whole body, more particularly of the thoracic parietes, and over the whole left side; and colliquative sweats. The respiratory murmur was extinct, or scarcely audible, in both sides of the thorax. In the whole right side, there was mucous *râle*, so distinct in the superior half as to merit the designation of cavernous. This *râle* also existed, in a slighter degree, in all the left side, except the inferior half of the lateral and posterior regions. The amphoric sound was, moreover, perceptible in these regions; pure in the inferior half, but mixed with the mucous *râle*, in the superior portion. The sound of the thoracic parietes was generally obtuse; but percussion was so painful, especially on both sides, that little use could be made of it. Great accession of fever was observed on the evening-visit. Death during the night.

NECROTOMY THIRTEEN HOURS AFTER DEATH.

Thorax.—More than half a pint of purulent serum in the left pleura; which was inflamed, thickened, and opaque, especially the pulmonary portion. The whole left lung condensed, impervious to the air, and adherent, by its vertex, base, and internal surface, to the contiguous parts. In the superior half of the posterior portion, caverns opening into the pleura, and communicating with the bronchial ramifications. White tubercles, variable in their consistence, discovered in all parts. Right pleura containing purulent serum, and exhibiting traces of inflammation more slight than in the left. Lung partly pervious to the air, some small caverns. Tubercles less abundant in the condensed portion: none in the sound part. This lung adhered to one of the intercostal spaces; with that exception, both were separate from the ribs. Much purulent mucus in the bronchia and their ramifications.

REFLECTIONS.

In this, as in the preceding case, the existence of a cavern opening into the left pleura, and the admission of the air into its cavity, was clearly indicated by the amphoric sound. As this sound supposes the presence of a certain quantity of fluid on which the air strikes upon its entrance, and, as there had been pains in the thorax, and other signs of pleuritis, the existence of empyema, in addition to the pneumo-thorax, could not be doubted.

The mucous and the cavernous *râle* accurately coincided with the existence of caverns in both lungs, and of the muco-purulent secretion in the whole, or greater part, of the bronchial tubes. It is worthy of remark that, in both cases, these sounds were combined, without any difference save that of strength. The same has been observed in many other cases; and the author concurs in the opinion of Andral, that the cavernous, the mucous or bronchial, as well as the crepitous *râle*, are merely degrees of the same sound, and dependent on the situation or cavity in which they are produced, and the quantity of fluid which it contains.

(To be continued.)

England.

(The following are the only articles of interest in the last two numbers of the *Medical Gazette*.)

POST-MORTEM HEMORRHAGE.—Mr. A. S. Taylor, in his lectures on medical jurisprudence, remarking on post-mortem hemorrhage, says, its occurrence formerly gave rise to the most superstitious notions, and even in the present day it often induces a coroner's jury to suspect that homicide has been committed. In order to explain this, and some other apparently vital phenomena connected with the dead body, reference must be made to those spontaneous changes which commence soon after death. When a person has died suddenly from violence or disease, it often happens that, within a short period afterwards, the whole of the cavities, including the veins, arteries, and cellular tissue, become distended and emphysematous, from the considerable extrication of gas which ensues. The gas collected in the abdomen pushes back the diaphragm, in consequence of which mucus issues from the mouth and nostrils, the face becomes swollen, the eyes bright and prominent, and the pupils contracted, owing to the blood having been forced back to the head and neck by the emphysematous state of the abdomen and viscera. It is owing to this cause that the contents of the stomach are sometimes discharged, escaping into the trachea, or externally by the mouth. That which, however, more immediately concerns us at the present time, is the development of these gases within the heart and vascular system, in consequence of which blood is forced out of a wound made in a vessel before death, long after the phenomena of life have ceased. When an attempt has been made to bleed a person immediately before death without success, and the operator has neglected to secure the opening, it frequently happens that, some hours after death, a large quantity of blood escapes by the wound—conveying to those who are uninformed on these matters the idea that the person had again come to life, but had died from the bleeding. An accident of this kind gave rise to considerable discussion on the occasion of the inquest held at Oldham, on the body of John Lees, killed in the Manchester riots, as also in the case of the Crown Prince of Sweden, who was suspected to have been poisoned. A similar flow of blood may take place from a large incised wound, made recently before death. This post-mortem hemorrhage is facilitated by pressure, and hence arose the ancient test of guilt, viz., the touch of the murderer.

PARACENTESIS THORACIS.—Dr. Hughes narrates a case of pneumo-thorax following an injury to the side, apparently unattended by fracture, in which pleuritic effusion supervened. Calomel and opium were exhibited internally until the mouth became sore, and the side was blistered, but without advantage. In consequence of the supposed injury to the lung itself, it was thought desirable not to draw off the fluid, but for a time to leave the case to nature, and to keep up the general health. The patient was allowed to get up and go into the air, and to take meat and porter. Blisters were occasionally applied to the side, and he took the iodide of potassium and liq. potassæ in bitter infusion twice or three times a-day. After this plan of treatment had been continued for a month, the chest was found to present the following signs:—The left side measured three-quarters of an inch more than the right, was scarcely at all raised during inspiration, was dull upon percussion, as high as the nipple before, and over the whole of its posterior surface. There was no separation or filling up of the intercostal spaces perceptible, as although very considerably reduced in flesh, he was still in good condition. The respiration was absent or distant, the voice was indistinct, and tactile vibration was absent inferiorly. The respiration was puerile below the clavicle, and bronchial with bronchophonic voice in the left interscapular region. The heart was heard and felt most distinctly on the right side of the sternum. No metallic ringing of the breathing, or of the voice, or cough, could be distinguished; the splashing of fluid was still audible, though it was much less loud than formerly, and gave the impression to the ear of a cavity nearly full. He usually lay upon his back, with the shoulders slightly raised, but could lie upon either side without inconvenience. The breathing was not hurried, excepting when he exerted himself. Paracentesis thoracis was then performed, and fifty ounces of turbid sero-purulent fluid were removed in a full stream, without the admission of air, or any act of coughing, but with the effect of causing slight temporary faintness. It was then thought desirable to stay the stream, and to allow the lung time gradually to expand. Plaster and a bandage were applied as usual, and he was desired to keep his bed, and to refrain as much as possible from talking for twenty-four hours. The next day he felt no inconvenience from the operation, but was relieved, and felt lighter, and the heart was removed from the right side to the posterior surface of the sternum. The pulse numbered 96, and the respirations 28. The operation was repeated on two succeeding occasions, after which he was so much improved, that he was allowed to go out of the hospital on leave. He did not return. Another case of pleuritic effusion is described by Dr. Hughes. The patient had been under treatment in the hospital about four months previously for pleuritic effusion of the right side, and had been discharged in three weeks free from complaint, with the exception of some remaining dulness and pleuritic creaking posteriorly. On his readmission the face was flushed, and the skin rather hot; the tongue loaded, but moist; the pulse 112, small, and feeble; the respirations 32; he had no pain when quiet, but the act of coughing, which was frequent, and accompanied with a scanty mucous expectoration, was attended with pain of the left side. He was able to lie flat in bed, and to turn to either side without inconvenience. Upon inspection of the chest the left side appeared evidently more rounded and fuller than the right; the ribs were imperfectly elevated during inspiration, and the intercostal spaces were almost upon a level with the ribs, so as to present nearly an even surface; they also afforded a sense of vibration rather than of fluctuation to the finger when the parietes were struck. The left side was dull upon percussion as high as the third rib, and to the centre of the sternum anteriorly, and over the entire posterior surface. Tubular breathing, increased shrillness, not loudness of the voice, and a decrease, not an entire absence, of tactile vibration, were observed in the greater portion of the dull expanse. But hoarse and puerile respiration was audible, and tolerable resonance upon percussion could be elicited in the infra-clavicular and acromial regions. The impulse of the heart could be felt on the left side, close to the sternum, but it could also be felt at least as distinctly on the right of the sternum, and much more distinctly at the scrobiculus cordis; its sounds and rhythm appeared to be natural; the comparative size of the two sides was not ascertained. With the exception of some bronchial rattles, the right side appeared to be natural; the posterior dulness which existed when he left the hospital had disappeared. He was bled and blistered, and mercury freely employed until salivation was induced, but ineffectually. There existed no evidence of the decrease of the effusion; on the contrary, there appeared to be direct evidence of its increase. The dulness existed up to the very clavicle; the heart's impulse was distinctly felt between the fourth and fifth ribs on the right side, and was barely perceptible on the left side of the sternum; and though the breathing was not more hurried, the countenance was depressed, pale, and of a leaden hue, and the expression was anxious; the tongue was loaded from the action of the mercury; and the pulse was feeble, frequent, and compressible. It was, therefore, thought desirable to draw off some of the fluid, so as to secure the future expansibility of the lung, if he should recover, but of which there appeared to be some doubt, as his case presented considerable danger. The exploring needle was accordingly introduced by Mr. Cock, and the presence of an abundance of serous fluid having been ascertained, a small trochar was passed into the chest, and forty ounces of clear dark-coloured serum were withdrawn. He was rather agitated by the operation, and coughed considerably while the fluid was being drawn off. During the forced expiration following the cough, there was a tendency for the air to enter the chest. The canula was consequently removed, though much more fluid might under other circum-

stances have been obtained without the admission of any air. He did not say that he felt relieved by the operation. Some improvement followed, and the use of mercury was persisted in. The effusion not decreasing, the operation was repeated, and thirty ounces of clear dark-coloured serum removed. It formed a transparent gelatinous coagulum upon cooling, became semi-solid upon being heated, and was of specific gravity 1030. Two days afterwards the bandage was removed; the entire anterior surface of the left side of the chest was resonant, and a portion of the lower part was tympanitic upon percussion (probably from the stomach); pleuritic rubbing was heard in the infra-clavicular and mammary regions, and a thrill from surrounding vibration, rather than the direct impulse of the heart, was perceived upon the right of the sternum, though the impulse was scarcely more distinct upon the left side. The posterior part of the lateral and axillary, and the whole of the posterior regions, were still dull upon percussion, whether he sat up in bed or lay on his stomach; no pleuritic rubbing was heard posteriorly, and but little tactile vibration was there observed, though the respiratory murmur was indistinctly heard over the greater part of the side. After this no further effusion took place and the man gradually improved, so as to be nearly recovered at the date of the report.

SCIATICA.—A case of sciatica is reported from University College Hospital, which was cured by blistering, and the endermic application of the hydrochlorate of morphia.

TUMOUR IN THE CHEST.—Mr. C. Taylor attended a lady, fifty years of age, who complained principally of symptoms referable to the digestive organs, and of dyspnœa. She could lie on either side, but most easily on the back; cough slight, and no expectoration; countenance turgid, hands cold, fingers blueish, pulse 100, and feeble. On physical examination, the right side of the chest was prominent and rounded, distinctly larger than the left, but without intercostal fulness; it was as dull as a board; posteriorly, no respiratory murmur was audible, but there was bronchial respiration to a limited extent between the scapula and spine. Voice modified, distant, and shrill. The left side posteriorly was preternaturally clear; respiratory mur mur puerile; the voice normal. Right side anteriorly was dull; no respiratory murmur through out; on the left side the voice was normal. The heart's sounds were regular and weak, but heard on the right side of the chest before and behind. Veins of the neck full; some whitish gelatinous matter was expectorated. It was regarded as a case of empyema, or extraneous growth in the pleura; and, on account of the patient's feeble state, ammonia and mild nourishment were allowed. The general distress and dyspnœa continued to increase, and the patient lay on her left rather than on her right side. No cough or expectoration present; drowsiness and delirium supervened, with slight œdema of the feet; the urine was albuminous on boiling. She sunk rapidly. The post-mortem examination was made fifteen hours after death. On introducing a trochar between the seventh and eighth ribs, below the angle of the scapula of the enlarged side, only a drop or two of clear fluid escaped, and when a probe was passed it came in contact with a hard and rather elastic substance. On withdrawal of the canula, more serous fluid escaped. On opening the chest, the right pleura was found to contain upwards of four pints of straw-coloured serous fluid; the lung, compressed upwards, did not exceed the size of one normal lobe, and was destitute of air; there were no tubercles. Below the lung, and occupying the chief part of this side of the chest, was a round smooth tumour, rather larger than a fœtal head, having the pleura reflected over it, connected with the right side of the bodies of the seventh and eighth dorsal vertebræ by an almost cartilaginous neck; but it was uncertain whether it originated from the bony substance of the vertebræ or the intervertebral substance; some old bands connected the pleura covering it, and the lung had recent bands of lymph connecting it with the upper part of the chest. The left lung was crepitant, but congested and œdematous. Heart small and atrophied. Pericardium and valves healthy. The liver, which was thrust down, was puckered, but otherwise healthy. Kidneys enlarged. The uterus had three or four tumours connected with it. The tumour weighed two pounds and three quarters; it was generally hard and firm in structure, but was softened down in the centre, containing a cavity with softened walls; externally it was of cartilaginous hardness. Dr. Gull had since examined its structure by the microscope, and found that the opaque white spots it its centre were apparently fat cells, becoming soluble on the addition of ether, which, on evaporation, yielded up fatty matter. In the more solid portion of the tumour similar cells (fat cells?) existed conjointly with a number of nucleated cells (malignant?). The structure of the uterine tumours was different, the cells being more simple, and no fat cells being anywhere discoverable.

CONGENITAL ABSENCE OF THE CORPUS CALLOSUM.—Dr. Ogier Ward describes a case in which there was congenital absence of the corpus callosum in a male illegitimate child, which survived about eleven months. It was subject to convulsions from birth, and although it could hear and see, gave no signs of intelligence. The brain was about five inches long by three and a half wide, and two and a half inches thick; it was not vascular, but was firmer than natural. The lateral ventricles were distended by about an ounce and a half of serum, which ran out on attempting to raise the cerebrum. The nerves were all perfect. The cortical portion was very superficial, and separable from the medullary part, apparently from the absence of convolutions to dovetail them together. The cerebellum was equally deficient in cortical matter. When the brain was taken out and laid upon the table, the two hemispheres fell asunder, even the tuber annulare splitting into two equal portions, the decussation of the optic nerves being the sole connection of the two sides of the cerebrum. The central portions of the brain were so rudimentary as scarcely to be distinguished. The whole contents of the skull did not weigh more than a quarter of a pound.

DISSECTING ANEURISM OF THE AORTA.—Dr. T. Thompson records a case of this rare disease, occurring in a gentleman, forty-five years of age, who had been previously subject to occasional attacks of rheumatism. Dr. Thompson was called in, in consequence of his suffering from severe pain in the abdomen, accompanied by bilious vomiting. The pain, although somewhat lessened, continued still severe the next day, in the early part of which he was seized with syncope, for the removal of which powerful stimuli were administered, and their use persisted in. Evidence of internal hemorrhage afterwards presented, and he died on the fourth day. The body was examined twenty-four hours after death. On opening the chest, attention was directed to the distended state of the pericardium, which contained about six ounces of blood, part of which was fluid, but a portion formed a layer of coagulum, enclosing the heart. A considerable projection of the cellular sheath of the aorta compressed the left pulmonary artery in the first inch of its course, and gave its aperture the appearance of a narrow chink. The coronary arteries were dilated and rigid, more especially the right one, which, about an inch from its origin, was about six-tenths (·65) of an inch in circumference. This rigidity was owing to atheromatous deposit, which, on tracing the artery from its commencement, became more and more conspicuous. The enlargement about the aorta was found to have been occasioned by the escape of blood into the cellular envelope of that vessel. There was no rent of the part adjoining the pericardium, but, judging from the situation of the principal ecchymosis and discoloration, it was sufficiently evident that the blood had escaped into the pericardium, between the pulmonary artery and the appendix of the left auricle. On cutting into the aorta, a rent about eight-tenths (·85) of an inch in extent was observable, passing through the internal and part of the middle coat of that vessel, half an inch above the free border of its posterior valve, at first nearly perpendicular to the valve, then for about three lines diverging to the left side, so as to assume a form like that of the clavicle. The lining membrane of the aorta was easily lacerable, and in many parts, especially near the arch, studded and tuberculated with atheromatous deposit; but there was no deposition or ulceration near the rupture. The edges of the laceration were ragged, and, when separated, disclosed coagulated blood, included between the layers of the middle coat of the artery, the transverse fibres of which were readily distinguishable. This separation of the laminæ existed entirely around the aorta at its commencement, and, extending upwards, surrounded one half of the arch behind the arterial trunks, afterwards nearly encompassing the vessel, excepting at the origin of the intercostal arteries, the inner and middle coats of some of which had indeed been entirely torn from their attachment to those of the aorta by the force of the intruding current of blood. The same current, proceeding by the outer and anterior side of the arteria innominata, encircled two-thirds of the right carotid artery as far as within an inch of its division into the external and internal branches. A similar separation extended along the posterior and left walls of the whole thoracic aorta, between the layers of the middle coat, and the effused blood could be traced downwards between the corresponding layers of the posterior wall of the vessel in its abnormal portion as far as the origin of the renal arteries. The heart was considerably enlarged and thickened, chiefly in consequence of hypertrophy of the left ventricle, the wall of which, on a level with the free margin of the aortic valves, was eight-tenths of an inch, and at the distance of an inch from the apex two-tenths (·23) of an inch in thickness; but its substance was deficient in firmness and colour, having the appearance of a weakened muscle. The valves of the heart and aorta were healthy, those of the pulmonary artery delicate and cribriform. There was no special or partial dilatation of the aorta; but this vessel was of considerable calibre, its circumference above the rupture measuring exactly four inches, whilst that of the pulmonary artery, near the valves, was only three inches and two-tenths. The abdominal viscera were healthy, with the exception of the kidneys, which presented in their substance a few indistinct granulations, and on their surface some cicatrices, as though from former scrofulous disease.

SILEX IN AN URINARY CALCULUS.—Dr. Venables describes the chemical analysis of a portion of an urinary concretion extracted from the male urethra, in which he found silex combined with the earthy phosphates. From his remarks, it appears that the presence of silex in such concretions is rare. He seems to refer its origin in such cases to its presence in many articles of food.

GALLATE OF LEAD AND POTASH.—Mr. Ollby has found that, on precipitating the base of either the acetate or nitrate of lead by a solution of potassa, and afterwards adding a few drops of saturated solution of gallic acid to the fluid, the oxide thrown down almost immediately assumed a pink hue, which, by the absorption of oxygen from the air, speedily became crimson, the latter colour being remarkably deep and shining. This crimson compound is perfectly soluble in an excess of the alkali, though the clear solution is not, as might be supposed, of so rich a tint as the solid precipitate: but, like the latter, its colour is rapidly heightened on exposure to the atmosphere. The same changes are produced by throwing down the oxide of lead from either of the above-mentioned salts by ammonia; but the colours are, in this case, less bright and more fugitive than when potassa is employed as a precipitant, the latter circumstance being probably attributable to the volatility of the former alkali. Soda gives rise to effects precisely similar to those produced by the employment of either potassa or ammonia. These coloured compounds are readily decomposed by nitric, hydrochloric, and other strong acids, and they are also destroyed by a very slight elevation of temperature, as well as by exposure for a few hours to the atmosphere; when, however, they have been deprived of colour by the action of an acid, the colour may be, in a great degree, restored, by adding more of the alkaline solution to the fluid so as to neutralise the acid. Mr. Ollby, from these curious results, suggests the joint employment of gallic acid and an alkali as a test for lead.

[The following are the only articles of interest to the profession in the last No of the *Lancet*.]

POISONING BY LEAD.—Dr. J. H. Bennett details the results of numerous cases of colica pictonum and lead palsy, which he saw treated by M. Gendrin by the internal administration of sulphuric acid, and which were nearly uniformly successful. As an useful test of the freedom of the system from the lead, and also as an adjuvant of the treatment, he advises the sulphur bath, and says no one should be considered safe until he has gone through the ordeal of that bath, with a perfectly white skin.

DISLOCATION OF THE LOWER JAW.—Mr. Levison recommends the use of the following apparatus in persons subject to luxation of the lower jaw. A flat band, composed of four layers of wash-leather, is accurately measured to the under part of the chin, with a cap to fix on the latter exactly, and so shaped as not to press on the trachea; and then it is neatly bound with ribbon. At one extremity there is a neat small buckle, not sown on the edge of the band, but on the flat side, the corresponding extremity having a neat doeskin strap, by which it is fastened at the top of the head, after being placed on the chin. This contrivance may be worn with security and ease. But as a preventive against the instrument being forced off during sleep, two pieces of ribbon or strong tape are sown on it at each side, exactly under the ears, and then they are tied behind just under the occipital process.

POISONING BY LIQUOR AMMONIÆ.—Mr. Williams describes a case of poisoning by liquor ammoniæ, which terminated favourably. The quantity taken was not known.

ABSCESS OF THE BRAIN.—Mr. Hancock states that he was called to a young female labouring under a disease of the ear. He found her complaining of intense agony in the right ear and side of the head, so severe that she was obliged to support her head by both her hands, her elbows resting on the table. He was informed that she had been subject to discharge from that ear, at intervals, ever since she was two years of age; but that she had been free from that annoyance for some few weeks. As she complained very much of pain in her teeth on that side, he was induced to examine her mouth, and found one of her teeth so much diseased, that he advised its instant removal, which was subsequently effected, with relief as to the pain in her mouth. He carefully endeavoured to ascertain whether there were any symptoms of disease of the brain, but could not discover any beyond the pain and sensation of weight in the head. She was perfectly sensible, could converse with her friends, and answered any questions put to her with the greatest readiness. Neither her arms nor lower extremities were affected; both sides of her face were natural, and she had perfect control over the sphincter muscles up to the period of her death. On the second day she complained so much of throbbing in the ear, that he was induced to introduce a probe to ascertain the state of the parts, and passed it nearly two inches into the organ without meeting with any obstacle. However, shortly after he left, he was informed that she felt something yield, which sensation was followed by a copious discharge of matter from the ear to the extent, as the friends informed him of nearly two ounces, with decided relief. He saw her three times a-day until her death; and he observed, that although he carefully watched for any symptom of paralysis, he could not detect any, even at his last visit, about three hours before she died. On the next day but one he examined the body. On removing the brain, he found, corresponding to the petrous portion of the temporal bone, an ulcer of the dura mater about the size of a sixpence, this ulcer being evidently produced by some sharp processes of bone growing out from the petrous portion, the condition of which appeared to be perfectly healthy. Upon cutting into the right hemisphere of the cerebrum, he discovered a very large abscess, implicating nearly the whole of the middle, and extending into the anterior and posterior lobes of that hemisphere, the abscess being contained in a very tough and thickened cyst. There was no communication between the cerebral abscess and the internal ear, the petrous portion, as he had observed, remaining to all appearance healthy. He next examined the internal ear, but could discover no signs of abscess in that situation; the lining membrane was thickened, but there was no trace of any collection of matter having been found within that cavity.

SERO-CYSTIC SARCOMA OF THE MAMMARY GLAND.—A case of this disease is reported from the practice of Mr. Lawrence, at St. Bartholomew's Hospital. The patient was a female, thirty-six years of age, and a mother. The tumour seemed to have been the sequence of a mammary abscess, and to have been of considerable duration. About a year prior to her admission into the hospital, a black spot appeared on its surface, which increased in size, and was lanced, when some dark-coloured fluid, like coffee, was discharged. Some time after this the integuments sloughed, and the disease became fungous. When admitted a reddish fungous mass, with narrow base, the size of the two fists, of tolerably firm consistence, and moveable upon subjacent parts, protruded from the lower part of the right breast. The surface, whence issued a sparing but thin and offensive discharge, bled readily when touched, and was occupied here and there by shreds of sloughy tissue and small coagula; towards the circumference it was cicatrised in parts with the integuments; the surrounding tissues were but slightly indurated; the nipple, in its natural situation, and above the tumour, was surrounded by a dark-coloured areola, and more prominent than natural. She suffered occasional darting pains, but the tumour was chiefly distressing from its weight, size, and tender surface. The diseased growth was removed by operation, and the wound thus made cicatrised readily. Upon making a vertical section, it was found composed of yellowish masses of firm homogeneous structure, amongst which were interspersed cysts of various sizes, containing serous fluid. The disease extended to the pectoral muscles, fibres of which, in immediate contact with the tumour, were firmer and whiter than natural, but not otherwise altered in character. About a year afterwards another tumour of a similar nature was removed from the right breast, and the patient did well afterwards, and left the hospital apparently cured. Mr. Holmes Coote, by whom the case is reported, observes that sero-cystic sarcoma, commonly regarded as a non-malignant affection, commences, according to Sir B. Brodie, by a dilatation of some of the lactiferous tubes. One or more cysts, containing a clear serous fluid, which, by pressure, may be made to escape by the nipple, are imbedded in the healthy glandular structure. The disease, which may attack both breasts simultaneously, is not attended with pain, advances slowly, and does not affect the absorbent glands. In this case twelve years elapsed between the first appearance of the tumour and the perfor mance of the operation; the patient, rather inclined to embonpoint, had enjoyed good health during the whole period. Next, firm solid matter deposited upon the exterior of the cysts, binds them together in a mass, and destroys their globular form. The contained fluid assumes a brownish or blackish hue, probably from admixture of altered blood-discs. At some point a cyst, larger than the rest, manifests itself externally as an elastic tumour, over which the integuments, if not divided by the knife, slough, and allow the escape of the fluid coffee-coloured contents. An albuminous or fibrous growth is formed upon the inner surface of the cavities, covered by a delicate membrane, rapidly becomes organised, and shoots forth as a vascular bleeding mass. The discharge, in the present case, was offensive in smell. The occasional bleedings, the size, weight, and tender surface of the tumour, are the chief circumstances which induce patients to submit to the operation of extirpation. Nature, however, makes some attempts at reparation. The cyst may burst, and heal, and burst again, and even when the fungous growth has protruded, granulations may arise, and cicatrisation may connect it in parts with the surrounding integuments. With reference to the relapse in this case, Mr. Lawrence stated that in private practice he had removed the mammary gland for simple hypertrophy, the operation being followed in a few months by the formation of a sero-cystic sarcoma, the extirpation of which was succeeded by genuine medullary cancer.*** The case under notice gives every reason to believe that it was malignant, and will ultimately be attended with a fatal issue. The second operation was uncalled for.

TRAUMATIC TETANUS.—Mr. Page describes a case of traumatic tetanus, following a gunshot wound of the left arm, in which he exhibited aconite with success. The symptoms of tetanus did not show themselves until three weeks after the injury, which was very severe, had been received. The aconite was given in the form of tincture, prepared by Dr. Fleming, three minims being the commencing dose, and it was used on account of its known influence in destroying muscular irritability, and its powerful sedative effects on the nervous and vascular systems. The quantity administered was afterwards raised to four and five minims, and with evident benefit, but the peculiar toxic effects of the remedy were produced, and, on the third day after the patient had taken twenty-seven minims in seven hours, he was found at 6, p.m. in the following state:—There was entire relaxation of the muscles, accompanied by extreme prostration, so that he was unable to move his limbs, and he could scarcely make himself audible; the skin was pale and cold, and covered with a clammy perspiration; the pulse very slow, extremely intermittent and irregular; the pupil was dilated and insensible, and the vertigo and confusion of ideas were great. To these symptoms was added the most extreme irritability, the slightest impression on the senses producing an effect similar to that which is observed in hydrophobic patients. The least noise, the moving of persons in the room, the opening of the door, the act of swallowing the saliva, severally induced a severe fit of convulsive shuddering. It was evident that the aconite had been continued to the fullest extent consisted with safety. The exhibition of a rather large dose of laudanum in mulled wine removed these symptoms, and the tetanus being still present the next day, though in diminished force, the aconite was resumed, with the addition of as much wine and nutriment as the patient could take. The next day the combination of opium with aconite was required, on account of excessive muscular irritability. The day after, the effects of the aconite becoming again evident, especially in the pulse, it was omitted, and opium, with sal volatile, alone given. It was afterwards resumed, and the disease gradually wore itself out.

Scotland.

LIGATURE OF THE SUBCLAVIAN ARTERY.—Dr. Mackenzie, in the *Northern Journal of Medicine*, details an interesting case of lesion of the axillary artery by burning, in which, after repeated hemorrhages, he applied a ligature to the subclavian artery with success. The patient was a married man, thirty-five years of age, of temperate habits, and the injury resulted from a fall while holding a red-hot poker in the left hand. In trying to save himself, he stretched out the left hand, which bringing the butt end of the poker to the angle of the room, where the wainscot and floor met, he fell with his whole weight on the red-hot point, which entered the right axilla, immediately behind the tendon of the pectoralis major. The poker was instantly withdrawn from the deep scorched wound, from which a few drops of blood escaped. Eight days afterwards a large eschar separated, and was followed by a sudden and copious gush of blood, which was arrested by tenting the wound. When seen by Dr. Mackenzie the day after, the surface of the wound, which was situated in the axilla, immediately to the inner side of the biceps, and behind the tendon of the great pectoral muscle, was about two inches in length and an inch in breadth, was covered with a grey-slough, and secreting a thin watery discharge. The skin in its neighbourhood was of a dark-red colour, and there was considerable hardness and infiltration around the shoulder and upper half of the arm. The hemorrhage recurred from time to time, and was more or less profuse, while the compression which was constantly used to repress it, was evidently doing mischief. By Mr. Syme's advice, therefore, the subclavian artery was ligatured, and it was further determined that if the operation failed to arrest the loss of blood, amputation at the shoulder-joint should be had recourse to. It was feared that it might be ineffectual on account of the free anasto-

mosis existing between the branches of the axillary and subclavian arteries. It proved, however, fully adequate for the purpose for which it was de signed; the ligature came away on the twentieth day, and the patient ultimately recovered. The only annoying symptom that followed the operation, was a slight pricking pain in the ulnar side of the wrist and hand, which, however, gradually diminished, and at the date of the report was very trifling. Dr. Mackenzie remarks on this interesting case that the untoward symptoms, which were to be apprehended after the application of the ligature, were gangrene of the limb, or a renewal of the bleeding from the wounded vessel, under either of which circumstances amputation must have been performed. The swollen and infiltrated state of the arm, with the feeling of cold and numbness of the hand, were conditions by no means promising for the vitality of a limb, in which the supply of blood was to be cut off from its main arterial trunk. The pressure of the compress upon the vessels and nerves of the axilla could not have been much longer continued without producing mortification of the limb; and the possibility of diminishing with safety, or altogether removing this pressure, after the application of the ligature, appeared to render the risk of gangrene much smaller by removing this obstruction to the venous circulation of the limb. The diminution of the swelling, which rapidly followed the cutting of the bandages and removal of the compress, showed this to be the case. A return of the hemorrhage from the axilla was certainly the danger to be most apprehended, and was, perhaps, the only real cause of anxiety for the issue of the case. The free anastomosis, existing between the branches of the axillary and subclavian arteries, is sufficient, in general, to admit of a return of pulsation in aneurismal tumours in this situation, at a shorter or longer period after ligature of the subclavian artery. Had the re-establishment of the circulation in the present case proved sufficient to renew the hemorrhage, amputation must have been immediately performed, as further pressure in the axilla would then have been inadmissible. The destruction of the coats of the vessel, however, Dr. M. believes to have been of very limited extent, as rapidly fatal, and much more copious hemorrhage than appears to have taken place in the present instance, often occurs from a very trifling lesion of the arterial coats. The surface of the wound, after the separation of the eschar, was healthy, and, as far as could be seen at the time of the operation, showed no further disposition to unhealthy action than was probably induced by the pressure of the compress. These circumstances led him to believe that the shrinking of the artery after the application of the ligature, and the contraction of the wound, which would probably take place after the removal of the compress, would prove sufficient to close the opening in the vessel, before the collateral circulation was established. Had the opening in the vessel, on the contrary, been of larger size, and produced by unhealthy or phagedenic ulceration, the prognosis must undoubtedly have been much less favourable than under the conditions above mentioned. The risk of secondary hemorrhage, on the separation of the ligature, was comparatively small, seeing that the artery at the point where the ligature was applied was sound; and all suspicions of the chronic disease of the arterial system, which is such a frequent cause of dread in similar operations for aneurism, were here absent.

Extraction of a Foreign Body from the Uterus.—Dr. Imlach records in the *Northern Journal of Medicine*, an extraordinary case, of which the following is an abstract:—He was first consulted in May, 1843, respecting a girl, then thirteen years of age, who had the habit of wetting the bed, and in whom there was also a little mattery discharge from the vagina. Some time afterward, when the girl was nearly sixteen, and menstruating regularly and copiously, she was admitted into a hospital, where the use of the speculum showed a profuse discharge of pus from the os uteri. She again came under Dr. Imlach's care, and he then examined with the glass speculum, and found the os uteri enlarged, irregular, and fungous-looking. The finger, however, proved the best explorer, and he discovered the os tincæ pretty high up, ulcerated, open, and of a very peculiar hardness. The point of the finger easily entered the uterus, and there to his astonishment he discovered a hard substance, which from its flat surface, circular shape, and the hole in the centre, he at once recognised to be a reel or prin. He then felt its stem, but could not dislodge it, for want of instruments. A few days afterwards, he removed it with a pair of long ball-forceps. He next made a very careful examination of the parts, but could discover nothing like a pouch, and was quite satisfied that the reel had been actually within the uterus, not partially but entirely. The os tincæ was very irregular, and would easily have admitted two fingers. The cavity of the uterus was large, its walls thick, soft, and well lubricated with the menses. The girl did not complain of any pain during the extraction. The reel was a common wooden one, one inch and a third in length, and five-sixths of an inch in the dimeter of its ends. Plenty of warm water was used with a female syringe during the next two days, after which he again visited the patient, and found that she had had little or no pain since the operation. He then examined both with the speculum and with the finger, and found the vagina smaller than before, and healthy; the os tincæ much contracted, firm, rather irregular in shape, and scarcely admitting the point of the finger. The purulent discharge had entirely ceased ever since that time, but she still occasionally wetted the bed, though not so frequently as she had done during the past six years. The girl declared that she did not introduce the reel into the uterus, but to this Dr. Imlach evidently, and very properly, attaches no credence. He considers it was introduced in the practice of masturbation, but even then, the extraordinary part of the matter is as to its entrance into the uterus. To solve this question, Dr. Imlach asks, to what extent is the mouth of the uterus open during coitus? for if it be then more patent than in the unirritated condition, repeated masturbation might force any such substance as the reel from the canal of the vagina into the cavity of the uterus.

Glycerine.—Dr. Seller, in the *Northern Journal of Medicine*, gives an account of glycerine, a remedy introduced to the notice of the profession by Mr. Startin in the treatment of certain forms of cutaneous disease, in the lectures published in the *Medical Times*. Glycerine is obtained by boiling litharge and oil together in a little water, when it separates, and remains dissolved in the water. Dr. Seller says that the travellers of the London whole sale drug-houses are already exhibiting samples, and soliciting orders for it over the country. Its usefulness depends most probably on its property of resisting evaporation, even at a considerable temperature. Mr. Startin says that a common plate wetted with it may be kept in an oven, side by side with a joint of meat, till the meat is cooked, without any sensible diminution in the quantity of the liquid. Hence, when applied to the skin, it remains moist, forming a coating or varnish, not distinguishable from the ordinary secretion of the part. A lotion composed of half an ounce with ten ounces of water, effectually prevents the skin from becoming dry. When used pure, it makes the part stiff and uncomfortable, so it answers best diluted. It is also added with advantage to poultices, and even to baths. Glycerine is an uncrystallisable transparent fluid, of the consistence of syrup, free from colour when perfectly pure, but usually of a yellowish tint, which may be removed by animal charcoal. It has no smell, the taste is sweet, and not unpleasant; it is heavier than water, 1·250 to 1·280. It dissolves in water in almost every proportion; it is also soluble in alcohol, while it is wholly insoluble in ether. It attracts moisture from the atmosphere, and this probably is partly the cause of its never drying up when spread out thin. At an elevated temperature it boils, part passing over unchanged, while the rest is converted into empyreumatic oils, acetic acid, and combustible gases, with a carbonaceous residue. When set on fire, it burns with a clear blue flame. It undergoes no alteration in the air, and cannot be made to ferment even by the addition of yeast. Nitric acid changes it with some difficulty into oxalic and formic acids. Nitrate of mercury affords a strong white precipitate; with chlorine, glycerine forms a white flocculent solid; and with bromine, a dense oily liquid. Boiled with solutions of salts of copper, it throws down metallic copper. The diacetate of lead gives no precipitate; and with the aid of heat, glycerine dissolves the oxide of lead. With potass it forms a compound soluble in alcohol. By sulphuric acid, it has been said, to be converted, as in the instance of starch, into sugar; but the real effect is the production of an acid-compound, the sulpho-glyceric acid. This acid with bases affords salts, exhibiting some analogies with the sulpho-vinates—these salts are soluble; the sulpho-glycerate of lime crystallises in long delicate needles. It may be obtained either from the residue of the process for making litharge plaster, or from the refuse of the soap-manufactories. When the original process by Scheele is followed, namely, by boiling litharge and oil with a little water, the water takes up the glycerine along with a portion of oxide of lead. The oxide of lead may be got rid of by sulphuretted hydrogen, and the water in part by evaporation; or, if it be desired of high specific gravity, by evaporation in vacuo, side by side with a vessel of sulphuric acid. When an animal fat is chosen, this is the best process. In the details of the first part of the process, the directions given in the pharmacopœias, under litharge-plaster, should be adopted. Dr. Ure, however, recommends, in the case of olive oil, no more than half the proportion ordered by the colleges. When an alkali is preferred to saponify the oil or fat, it should be in the caustic state—the glycerine will be found in the mother liquor along with a portion of the alkali. To saturate the alkali, sulphuric acid should be added as soon as the soap separates, and any excess of the sulphuric acid is then to be neutralised by a little carbonate of baryta. Next the liquid is to be filtered and evaporated to the consistence of syrup, and, after the addition of alcohol, it is to be filtered again. The alcohol dissolves the glycerine, leaving the sulphate of the alkali, and the sulphate of baryta as a deposit. This is the process as directed by Berzelius, but it is manifestly unfit to afford an article for the market. Tartaric acid may be taken here instead of the sulphuric acid, but alcohol is still requisite to separate the glycerine. For external application, the presence of a small quantity of the oxide of lead, or of caustic alkali, will not often be an objection in cutaneous diseases, and if it were, the oxide of lead might be separated sufficiently by sulphuric acid; nor would the caustic alkali, after being changed to a sulphate by the same acid, act injuriously. Glycerine consists of carbon, hydrogen, and oxygen with water, ($C^6 H^7 O^5 + HO$)—and it has been regarded as a hydrated oxide of a radical glyceryl ($C^6 H^7$) not yet separated. This oxide is further described, as a base analogous to the oxide of cetyl in spermaceti, and cerain in bees' wax. This base, united with the fatty acids, constitutes oils and fats—thus margarine is pronounced to be the bimargarate of glycerine, stearine the bistearate of glycerine, oleine the binoleate of glycerine, butyrine the butyrate of glycerine, &c.

Anthrakokali.—In an article, published in the *Northern Journal of Medicine*, entitled a Summary of the Remedies applicable to the Cure of Chronic Eruptions, Dr. Seller says, when speaking of anthrakokali, this substance was introduced several years ago, by Dr. Polya, of Pesth. It is prepared by adding hydrate of lime, to a solution of carbonate of potass with fourteen waters, in a sufficient quantity to set the potassa free; and then filtering and evaporating in an iron vessel, till the fluid assume the appearance of oil, when the residue is to be mixed with coal in fine powder, in the proportion of five parts for every six parts of carbonate of potass employed. The iron vessel is then to be removed from the fire, and stirring kept up till the contents are changed into a black homogeneous powder. It is then to be put into well-stoppered bottles. Dr. Polya prescribes two grains of this powder three or four times a-day in liquorice-powder, or carbonate of magnesia. An ointment is made by adding sixteen grains to an ounce of lard. According to Polya, this compound has the same specific effect over the tettery principle which mercury has over syphilis, sulphur over scabies, and iodine over scrofula. Polya's views have not been confirmed, but Gibert thinks it, as an external

application, a useful moderate stimulus, for example in psoriasis when it has reached its second stage.

Fuligokali.—In the same article, there is a notice by Dr. Seller of fuligokali, a preparation of soot and potass. Gibert finds fuligokali superior to anthrakokali. He has employed it both internally and externally. As an external application it is resolutive, detersive, and stimulant. Its use is in the various forms of tetter, and Wilson says he has found it particularly successful in the treatment of psoriasis palmaria. The following is the mode of preparing the substance. Boil one part of caustic potass with five parts of soot in a sufficient quantity of water for an hour. When the solution cools, filter, evaporate, and dry. The powder or scales obtained must be kept in a dry place, secured in well-stoppered bottles. The ointment employed by Gibert consists of from a scruple to half a drachm united with an ounce of lard. A sulphuretted fuligokali is obtained by heating in a little water four parts of sulphur with fourteen parts of caustic potass, and, after their solution, adding sixty parts of soot. Evaporate, and dry, and keep the resulting compounds with the same precautions against moisture as the fuligokali. It is to be suspected that all these preparations, the anthrakokali, the fuligokali, and the sulphuretted fuligokali, owe their efficacy chiefly, if not exclusively, to the alkali which they contain.

Cocculus Indicus.—In the same article, Dr. Seller thus speaks of the cocculus indicus. An ointment of this drug, a formula for which is now given in the Edinburgh Pharmacopœia, has been used with much benefit, chiefly in the early stage of several forms of porrigo, as in porrigo furfurans, after the removal of the scabs in porrigo lupinosa, and in porrigo scutulata before it has become dry. The ointment should be applied night and morning, and should be washed away with soap and water, at least once a-day. In some of these affections an ointment of picrotoxia has been substituted, and Dr Christison thinks that such an ointment might answer better for all of them. The picrotoxia ointment consists of ten grains of the picrotoxia to an ounce of lard.

Apoplexy.—At a meeting of the Medico-Chirurgical Society of Edinburgh, Dr. Scott made some remarks on apoplexy connected with obstruction in the veins and sinuses of the brain. The case brought before the Society was that of a young lady, who had been seized with paralysis of the left side of the body, with coma. She died in thirty-six hours. In the right hemisphere of the brain a clot of considerable size was discovered, surrounded by broken down cerebral substance; from this a large vein, filled with black and firmly coagulated blood, was traced into the longitudinal sinus. The sinus itself, as well as the lateral sinuses, was filled with firm clots, partly of blood and partly of lymph. These Dr. Scott considered as not being of recent formation, and to have been the cause of the rupture of the vessels of the brain. The preparation of the vein was exhibited. Dr. Scott stated that he had seen several cases of the same kind in young subjects, and he wished to draw a contrast between such cases and those arising from diseased arteries at a more advanced age.

Ireland.

Paralysis from Arsenic.—Dr. Corrigan, in the *Dublin Hospital Gazette*, describes, briefly, a case of paralysis of the upper and lower extremities occurring in a man, as the sequela of a (poisonous?) dose of arsenic taken by mistake for flour. Mercury was exhibited internally until ptyalism was produced, but without benefit. The firing iron was then applied along the spine, and over the thighs and legs, so as to produce superficial scorching, and was used daily. The man in a few days was able to walk, and had regained considerable power over the arms. Strychnia, in the dose of one-sixteenth of a grain, was then given internally, and at the end of three weeks from the first use of the firing-iron, all treatment was discontinued. The man was, however, retained in the hospital a fortnight longer, lest any relapse should occur. At the date of the report, the latter end of last February, he was in possession of perfect health and strength. In commenting on this case, Dr. Corrigan pointed out the mode of using the firing-iron, and the reason for giving it a preference over other counter-irritants. The iron used is very portable, consisting of a thick iron wire shank, of about two inches long, inserted in a small wooden handle, having on its extremity, which is slightly curved, a disc or button of iron, a quarter of an inch thick, and half an inch in diameter—the whole instrument being only six inches in length. The face of the disc for application is quite flat. This, trifling as it may seem, must be attended to. In the French cauterising irons, the buttons for cauterising are spherical, and the consequence is, that they must either be pressed long and deeply into the skin, to bring them in contact with an extent of surface equal to their diameter, or they can be made only to touch at a single point. The only other portion of apparatus required, is a small brass spirit lamp, so small that it can be carried in the waistcoat pocket. To use the instrument, it is only necessary to light the lamp, and hold the button of the instrument over the flame, keeping the fore-finger of the hand holding the instrument at the distance of about half an inch from the button. As soon as the finger feels uncomfortably hot the instrument is ready for use, and the time required for heating it to this degree is only about a quarter of a minute. Its application is effected as quickly as possible, the skin being tipped successively, at intervals of half an inch over the whole affected part, as lightly and rapidly as possible, care being always taken to bring the flat surface of the disc fairly in contact with the skin. In this way the process of firing a whole limb, or the loins, making about one hundred applications, does not occupy a minute, and the one heating by the lamp suffices. Each spot the iron has touched immediately becomes of a glistening white, much whiter than the surrounding skin. In the course of a quarter of an hour, or sometimes of a very few minutes, the whole skin become of a bright red, and the patient feels a glow of heat over the part. The iron is never rendered red hot. It is, indeed, very little hotter than boiling water, and Dr. Corrigan never makes an eschar with it, and very rarely indeed raises a blister. There are merely seen upon the skin next day a number of circular red marks, the cuticle not even being raised, and the surface being ready, if required, to receive a fresh application, which is of no trifling consequence where such an extent of counter-irritation has been used, there being no discharging surface to interfere with the motion of the limb, or the comfort of the patient. Indeed, in most cases, the patient is quite unconscious of what has been done. Dr. Corrigan strongly recommends this plan of firing as being preferable to other means of counter-irritation, because it can be applied so rapidly and so extensively, and he says his clinical clerks prefer it for themselves when affected with local muscular rheumatism, as being the least troublesome, the most rapid, the least painful, and the most effectual. Dr. Corrigan advises it in lumbago, sciatica, neuralgia, and paralysis.

Pitting of Small-Pox.—Dr. Tyler, in the *Dublin Hospital Gazette*, states that he employed the Vigo plaster with perfect success to prevent the pitting of the cicatrices, in a case of variola of a very formidable character.

Pituitary Catarrh.—Dr. Evans, in the *Dublin Hospital Gazette*, describes a case of pituitary catarrh, combined with extreme cachexia, in treating which, there being no counter-indicating gastric irritation, he gave chalybeates and vegetable tonics. Under this plan the patient's strength increased, the pulse diminished in frequency, the hectic subsided, and the bronchial secretion lessened. With respect to the prognosis of pituitary catarrh, he remarks that cases of this kind, which are very common, are apt to produce vesicular emphysema, or to terminate in the development of tubercles.

The cholera, while within ten days' journey of Teheran, has suddenly been arrested. The winter, which had been previously very mild, had become rather severe, and there had been a fall of snow.

Oxalate of Lime in the Urine.—Mr. Stallard narrates two cases illustrative of the great irritation in the urinary organs induced by the presence of oxalate of lime in the urine.

ORIGINAL LECTURES.

A Course of Lectures on Hernia,

By JOHN FLINT SOUTH, Esq.,

Surgeon to St. Thomas' Hospital, and Professor of Surgery to the Royal College of Surgeons.

(Delivered in the Theatre of the College, and revised by the Professor for the Medical Times.)

Lecture I.

Interest of the subject—Frequency of rupture—Attention given to it by Pott, Cline, and Astley Cooper—Information afforded by Petit, Ledran, Scarpa, and Jules Cloquet—Work on Ruptures by Mr. Lawrence, and recent Work by Mr. Teale, of Leeds—Writings by Cheselden, Gooch, Cheston, White, Bromfield, and Pott—Wiseman—Value of researches by Paré, Franco, Vigo, Guido de Cauliaco.

Definition of Rupture: Abdominal ruptures—Division into thirteen kinds—Comparative ferquency of the different kinds in the two sexes—Ruptures, either original or acquired—Conditions of a rupture—Sac: Variations in thickness—Predisposing causes of rupture—Immediate causes—Ruptures of three kinds: Reducible, incarcerated, strangulated — General observations on reducible ruptures: Symptoms—Shape and appearance—Size—Effects of sneezing and coughing—Disappearance of reducible ruptures on lying down—No constitutional symptoms when reducible or reduced—Effects when confined in the sac—Circumstances distinguishing the contents of a rupture—Fallacy of these signs.

Treatment of reducible ruptures: The truss—Requirements in the truss—Petit's observations on the truss—Effect of the pressure on the sac—Suspensory bandages.

Mr. President and Gentlemen,—I have selected rupture as the subject for consideration in the course of lectures I have now the honour to deliver before this College, believing it to be inferior in importance and interest to no one of the several diseases which fall under the care of the surgeon. It must be allowed that it is one of the most frequent ailments with which we have to do; but its commonness is one great cause of its importance, and another is presented in the necessity for an accurate knowledge of the complaint, in order to the often immediately required decision as to its treatment, the hastening or delaying of which, or it may be even of an operation, only for a very few hours, rendering it less or more dangerous, and restoring the patient to health, or devoting him to almost certain death.

The importance of the subject is further shown by its having attracted the attention of some of the greatest practical surgeons of this country—Pott, the elder Cline, and Astley Cooper. Of these highly-gifted men, Pott and Cooper only have given to the public, in a written form, the results of their observation and experience. Their excellent treatises on rupture, and more especially the magnificent work of Cooper, have long been, and will doubtlessly continue to be, our authorities on this subject. To the latter, especially, we are indebted for the thorough knowledge of femoral rupture, for the discovery of that peculiar covering of this rupture, to which he gave the name *fascia propria*, and of the true seat of stricture in this dis contradiction of the celebrated Spanish Gimbernat. It is much to be regretted beyond his lectures, there is no account of the labours of Mr. Cline in reference to rupture, for that he specially directed his attention to it is proved by the preparations he made, several of which are still in the museum of St. Thomas' Hospital, for the purpose of illustrating one of the two courses of lectures which he delivered on this subject, at Surgeons' Hall, in the year 1781 and 1782, when he held the office of professor; and

it is probable that he was induced to select his subject, in consequence of having, in 1777, discovered in a Chelsea pensioner, whose body he examined with Mr. Gunning, the existence of that form of inguinal rupture, now generally named "direct." Mr. Lawrence's work on ruptures, originally one of the essays sent in for the college prize, and subsequently enlarged considerably by the results of his reading and his own great experience, is a very excellent and practical work. And I have also much pleasure in directing your attention to the recent publication on the same subject by my old friend and fellow-student, Mr. Teale, of Leeds, which has added fresh reputation to his already highly deserved professional character, and sustains the high rank which the surgeons of Leeds have for so many years held in our profession.

Nor in making mention of our own countrymen, must we overlook the valuable information afforded by Petit, Ledran, Scarpa, and more recently by Jules Cloquet. In regard to Petit, it is much to be regretted that his treatise is not more commonly adverted to, as it contains a mass of personal observations and information of great practical utility.

I would here take the opportunity of impressing upon the younger part of my audience, many of whom, I trust, have determined to attain the honours of this college, that a large store of knowledge is ready to their hand in the surgical writings of the last century, more especially of the French school, for, with the exception of Cheselden, Gooch, Cheston, White, Bromfield, and Pott, English surgeons, prior to Mr. Hunter, were little better than copyists or commentators on French surgery. Exception also must be made of the "Several chirurgical treatises" of the illustrious Wiseman, who was fully equal, if not superior, to the French surgeons of his time—the middle of the seventeenth century—when the French Academy of Surgery was founded. These authorities, with the exception of Pott, are now rarely referred to, though full of practical information—a circumstance much to be regretted, and which I should gladly see repaired, as the study of these writers, and not merely of them, but even of Paré, Franco, Vigo, Guy de Chauliac, and others of still earlier date, could shew that much had been done for surgery in reference to the observation of disease, and the performance of operations, which have been put forward by modern writers, who have filched from the stores of these now little read fathers of our profession, without compunction appropriated to themselves, and reproduced as their own, opinions and operations which were of old date, often correct and useful, but which had been gradually superseded by that fondness for change and novelty which mankind generally, and our profession not least among the number, is too much disposed to favour.

A RUPTURE is the bursting forth or breaking out of any bowel from the cavity in which it is naturally contained. It may happen in either of the great cavities of the body, the belly, the chest, or the head; but the term by which the disease is designated is more especially employed in reference to those protrusions which take place from the belly, and are commonly known as HERNIÆ.

Of abdominal ruptures, thirteen kinds are commonly described; of which nine, escaping from the muscular cavity of the belly, form external swellings, whilst the tenth is not to be seen, as it passes into the chest. The other three never leave the belly, but merely pass through originally or accidentally-formed holes in one layer of the doublings of peritoneum which connect the chyle-making intestines to the spine, and thus, though within the walls of the belly, are on the outside of the peritoneum.

The nine externally appearing ruptures are the

Inguinal,	Ventral,	Perineal,
Femoral,	Thyroid,	Vaginal,
Umbilical,	Ischiatic,	Rectal.

The one internal rupture is the Phrenic. The other ruptures are the Mesenteric, the Mesocolic, and Meso-rectal.

As to the frequency and predominant kind of abdominal ruptures in the sexes, an interesting statistical account has been given by Mr. Lawrence, from the register of the City of London Truss Society, during a period of twenty-eight years: whence it is shewn that—

		IN MEN.		IN WOMEN.
Of 76,730	abdominal ruptures of all kinds, there were	65,031	....	11,699
	Or a proportion of	$5\frac{1}{2}$	....	1
39,419	were single inguinal, of which	38,322	....	1,097
	Or a proportion of	35	....	1
25,252	were double, of which	21,966	....	286
	Or a proportion of about	134	....	1
64,671——				
6,210	were single femoral, of which	699	....	5,511
	Or a proportion of rather more than	1	....	9
1,777	were double, of which	169	....	1,608
	Or a proportion of	1	....	$10\frac{1}{2}$
7,987——				
3,439	were umbilical, of which	664	....	2,775
	Or a proportion of	1	to rather more than	5
624	were ventral, of which	209	....	415
	Or a proportion of nearly	1	....	2
5	were thyroid	1	....	4
4	were perineal	1	....	3

and that of the total number, inguinal ruptures were more prevalent than the other kinds in the proportion of nearly seven to one.

Ruptures may be either *original*, that is, existing at birth, and therefore called *congenital*, in consequence of certain apertures from the belly, which exist during fœtal life, continuing unclosed, as especially in umbilical and congenital oblique inguinal rupture; or they may be *acquired* at any after period of life, under which circumstances, although either kind of rupture may occur, yet inguinal rupture is by far the most prevalent of all in both sexes, and next to it femoral rupture in females, as has been already shown.

The conditions of a rupture are—a protrusion of bowel, either gut, omentum, or bladder, or any or all of them, enclosed in a sac-like extension of the peritoneum which they have driven before them, in escaping from the belly, and which sac once formed has coverings, called its coats, consisting of the parts beneath which it is thrust. To this general condition as regards the peritoneum, there are perhaps two exceptions:—umbilical rupture has probably no peritoneal sac, and phrenic rupture has not a sac of any kind.

The peritoneal sac varies in thickness: at the first production of an acquired rupture it is thin, but afterwards it is uncertainly thin or thick, unless a truss has been worn, when it is generally thickened; the bulk of the rupture does not, however, necessarily induce thickening of the peritoneal sac, but rather the contrary. But there are instances in which the peritoneal sac is not merely thickened, but has a cartilaginous character, and in some very rare cases it is said to be converted into bone, of which there is an example in a femoral rupture in St. Thomas' Museum; this, however, is not the case, the presumed ossified sac is merely a small ossified absorbent gland.

The thickness of the coverings of the sac is also generally subject to great variety; but in general the muscular coat which a scrotal rupture obtains from the cremaster muscle is of proportionate thickness to the bulk and weight of the rupture, the muscular fibres being more than usually developed for the support of the additional weight thrown upon them; but even this is not always so.

The *predisposing causes* of rupture are—weakness of the walls of the belly, either from the general want of tone in the muscles, or from their thinning by distension in pregnancy, dropsy, or when large tumours have formed in the cavity of the belly, or in consequence of rapid emaciation, especially after corpulence. A blow, by which the abdominal muscles are torn without breach of the skin, or a stab, shot, or other wound, in which both skin and muscles are divided, are almost invariably followed by protrusion of the bowel, after healing of the wound, and the patient getting about, although previously no rupture had been noticed, or, if observed, had been prevented.

The *immediate causes* of rupture are—excessive pressure on the bowels by violent contraction of the abdominal muscles in straining at stool or making water, in severe vomiting, coughing, or labour; also in violent exercise, as riding, climbing, running, rowing, or the like, or in pushing and lifting or carrying heavy weights. Blows on the belly, even when the walls are uninjured, will also cause rupture, and wounds of the walls of such size that the escape of the bowel cannot be checked.

Ruptures are of three sorts:—

First, reducible, in which the protruded bowel passes from the belly into the sac, and returns into the former cavity, according to the posture of the body; or which, if for a time it be retained in the sac, can be returned by manipulation into the belly, and in both cases is usually not attended with marked symptoms.

Secondly, irreducible, or as it may be justly called, incarcerated, in which the protruded parts are, from various causes, as entanglement by bands stretching across the sac, or adhesion to it, prevented returning into the cavity of the belly, either by posture or manipulation, yet without interference with their functions, and consequently without symptoms.

Thirdly, strangulated, when, either without or with incarceration, such constriction of the protruded bowel is produced by one or other part of the peritoneal sac, or of an accompanying bowel, that the natural functions of the bowel are partially or entirely suspended, and give rise to a peculiar and characteristic set of symptoms corresponding in severity with the mischief going on in the protruded bowel, and which, unless relieved, has a fatal issue.

GENERAL OBSERVATIONS ON REDUCIBLE RUPTURES.

Symptoms.—The first sign of a rupture is the appearance of an unnatural swelling on any part of the wall of the belly, or its immediate neighbourhood, where ruptures are known to present. The swelling may have either existed at, or very speedily after, birth, as in umbilical or congenital inguinal rupture, or it may appear suddenly at any time of life, according to the circumstances under which it arises. It varies in form according to its position: is sometimes pear-shaped, as in scrotal rupture; sometimes irregularly hemispherical, with a broad base proportioned to its size, as in umbilical rupture; or more rounded, less prominent, and with a narrower base, as in ventral rupture; or of an oval form and spreading base, as in femoral rupture. The size of the swelling is generally in proportion to its duration, usually being at first small, and subsequently increasing; but this is liable to variety. And, indeed, some ruptures are ordinarily exceptions to this rule—as, for instance, femoral ruptures, which for the most part either at first, or very soon after their appearance assume their full, or their nearly full bulk, and increase but very little after. The ruptures which acquire the greatest size are the umbilical and the scrotal, in either of which occasionally the greater part of the bowels escaping from the cavity of the belly become lodged in the rupture-sac. The size of the swelling is increased by exertion, the pressure of the abdominal muscles, and the descent of the diaphragm, thrusting the bowels from the belly into the sac. This may be observed in hallooing, sneezing, or coughing, even with little effort, and on the temporary enlargement then ensuing, the rupture is, in surgical language, said "to dilate." This dilatation becomes a symptom of rupture, and by slight coughing is rendered perceptible to the hand, when grasping the tumour, by the impulse communicated to it, though the

protrusion be not so great as to produce to the eye any apparent increase of size. Reducible ruptures are also characterised by their appearance when the body is erect, and their disappearance on lying down, consequent not merely on the abdominal muscles ceasing to compress the bowels and to force them from the belly, but also on the pull on them by the bowels still in the belly, assisted even by their own peristaltic action. The readiness with which the bowel passes from one cavity to the other depends on the size of the aperture and the quantity of bowel forced out, and whether the latter be little or much distended with air or fæces. If it be much distended it will not return, even when the patient lies down, until its contents have been emptied; and if this be done, even in the erect posture, the rupture may often be reduced without difficulty, although it descends again immediately that the fingers are removed from before the mouth of the sac.

Beyond these outwards signs, ruptures, while reducible and reduced, produce no constitutional symptoms; but when protruded, either in consequence of no truss being worn, or when of such size that a truss is useless, then after exertion there is much wearisomeness, and if the bowel be for a time confined in the sac by a greater quantity than usual having descended, or by the gut which is down being loaded with fæces, or much distended with air, uneasiness and dragging of the stomach, squeamishness, or even vomiting, and irregular relief from the bowels, or even constipation, may occur, and continue till the rupture has been reduced, when they cease.

Surgical writers and teachers have not unfrequently mentioned certain circumstances as distinguishing the contents of a rupture from each other — thus one swelling regular, elastic, and affording a gurgling feel or even noise when pressed between the fingers and thumb is held to be an intestinal rupture; whilst another which is irregular, has a doughy feel and does not gurgle, is thought to be an omental rupture. Daily experience, however, proves that these are most uncertain distinctions, and not to be relied on. The gurgling is often absent in intestinal rupture, and may exist in the omental, especially in old and large ruptures, in which the lubricating fluid of the peritoneum is not uncommonly increased in quantity, and, descending into the sac, collects, and moving about when squeezed produces gurgling or fluctuation, just as would a bladder partially filled with water. The doughy feel is often merely effusion of serum into the cellular tissue resulting from the patient's repeated efforts, or the surgeon's coarse handling of a rupture, which, though only retained in the sac from the causes already mentioned, requires rather more than ordinary effort and skill for its reduction. Further, there may be both gut and omentum in the sac at the same time, and both or neither of the described symptoms may exist. It must, however, be admitted, when a rupture is of large size and its walls very thin, if there be much gut down, its crawling peristaltic motion may not unfrequently be felt, and occasionally even seen through the skin. In those rare ruptures, into which the bladder has either dropped or been dragged, the symptoms mentioned, to wit, constant disposition to void the urine in consequence of the weight of the protruded part dragging on that portion of the bladder which retains its natural place, and diminution of the size of the rupture-swelling merely by raising it, and so decanting the urine contained in the protruded part of the bladder from it into the unprotruded cavity of that organ, may doubtlessly occur, and afford a good distinguishing character of the sort of rupture. But inasmuch as this unnatural condition of the bladder is almost invariably the result of an intestinal or omental rupture, and accompanied with one or both of these, so it becomes even more difficult or even impossible to distinguish between the contents of the rupture-sac.

Treatment.—The objects in treating reducible ruptures are—to retain them in the belly by preventing their descent, and to avoid all efforts which may promote their escape from the belly, and, tending to increase their bulk, may enlarge the mouth of the rupture-sac so considerably that no remedy is sufficient to prevent their bursting from their proper cavity.

To prevent the protrusion of a rupture various kinds of trusses are employed, consisting of either a pad, to cover and press against the aperture by which the bowel escapes, or a simple bandage, to keep it in place, or a pad attached moveably or immoveably to a half-hoop spring, one end of which rests upon the *sacrum*, whilst the other presses the pad upon the seat of the rupture. I prefer a fixed pad, as, if properly fitting, it keeps its place best, and makes most steady pressure.

Although the permanent cure of a rupture by the use of a truss is not to be expected, when the protrusion first occurs in adult life, yet the attempt to effect it should not be lost sight of, more than in young persons The application of the truss is, therefore, not simply to prevent the escape of the bowel from the belly, but also with the object of producing the union of the sides of the passage through which it passes, and thus destroy the track by which it has travelled.

To effect this, the truss-pad must have such size and position as to cover both the aperture by which the bowel escapes from the belly, and also the passage through which it runs towards the surface of the body; and it must also be retained in such position, with sufficient pressure, to keep the walls of the passage in close and permanent contact, which has the only chance of being effected by the attachment to the pad of a spring of sufficient strength to countervail the disposition to protrude which the action of the abdominal muscles is constantly exciting in the once-protruded bowel.

Two very important points are connected with the use of trusses, upon which, indeed, the benefit to be derived from them entirely depends: first, that they should always fit well, and, secondly, that they should never be removed when in the erect posture.

1st.—Unless a truss fit well it is of no use, and even hurtful. It must be remembered that the patient's condition is continually varying, and that his form is constantly undergoing a less or greater change, more especially in young persons; consequently, a truss which fits well, and serves all the required purposes when first applied, will, in growing children particularly, cease to do so in the course of a few months, and need re-adjustment. It must, therefore, from time to time, be looked after, and such alteration made as is requisite. In adults, in whom there is less change of form, except so far as depends on stoutness, the truss requires attention, because, in consequence of exertion, more especially in labouring people, the rupture oftentimes soon overcomes the resistance of the truss, the spring of which needs to be strengthened in proportion.

Petit makes some very valuable observations in regard to the use of trusses. He remarks that "it is very common, after two or three days, to find that some part of the rupture has slipped from beneath the truss, or rather that there is a swelling of the spermatic vessels, or even of the testicle itself. If it be ascertained in these cases that the rupture is well kept up by the pad, we must find out the cause, which is commonly that the thigh-strap is too tight, and it must then be slackened. If, however, the pad be too wide, or its edges too thickly stuffed, and it compress the vessels, the bandage must be changed, and a pad narrower and with more shallow edges must be applied." He further observes that "the omentum is the only part which protrudes, as it may be said, *incognito*, because it may be compressed without the patient's notice, inasmuch as it is not sensible; instead of which, when the gut descends, the patient immediately perceives it, by the severe pain and nausea it produces. But more commonly the omentum is protruded; for there is the difference between the two parts, that the intestine protrudes with great difficulty, and readily returns, whilst, on the other hand, the omentum escapes with readiness, but is difficult of reduction."

It is, however, important that the pressure of the truss should not be excessive. "There is less risk in its being little tight than being too tight," says Petit; "it is wise in the surgeon to avoid this excess, for I have often seen gangrenous abscesses form, in which I have found putrid omentum from this cause," and he mentions two cases, one of inguinal, and the other of umbilical, rupture, in which this occurred, but which, however, recovered after suppurating.

2nd.—The truss should never be removed day nor night, excepting for a few minutes, and when the person is recumbent, for the purpose of cleanliness, and it should be re-applied before he change his position. Unless this advice be attended to strictly, a young person especially may in a few minutes have all the benefit of that narrowing of the upper part of the rupture-sac, which has been slowly attained during months, or even years lost, his cure retarded, or even actually prevented, and the rupture rendered permanent by being again forced down when its sac is unsupported.

Those persons born with ruptures, or in whom they occur at an early period of life, may generally be cured, if a truss be constantly worn for some years; but when ruptures are acquired at the adult period they are rarely cured, and still less frequently, if ever, in more advanced age.

In regard to the cure of ruptures by wearing a truss, Petit says, "We know that the sac disappears little by little during the use of the truss, when it well retains the parts, and that more who wear them are not cured, unless they use them till the sac has entirely disappeared (effacé), or, to explain myself better, until the portion of peritoneum which forms the sac, has become adherent to the intestine, or has entirely conformed itself to the rest of that membrane within the belly, resuming the polish, extent, and natural elasticity. This really happens, as I have seen on opening many bodies who have died of other diseases, which during youth have been cured of rupture by wearing a truss. I do not say this is always the case, but I have very frequently noticed it." That he certainly means the peritoneal sac, in both instances, returns into the belly is proved by the question he subsequently asks and answers:—"Is it possible that these adhesions are destroyed? Certainly not, they are always the same; to understand what happens, let us revert to what I have already observed in speaking of the hernial sac. I have said that in ruptures cured without operation, the portion of peritoneum forming the sac returns into the belly, and resumes its level with the rest of the peritoneum; but in ruptures with adhesions, treated as I have just mentioned (first with a cup and then with a pad truss), if these parts return, the sac must also return with the adhesions it has contracted with those parts."

It would seem, however, that on this point Petit is in error; for when ruptures are cured, not the whole sac, but merely that part of it pressed on by the pad of the truss is obliterated, and the cavity below it still remains. This certainly happens in inguinal and femoral rupture, but I have not seen any dissection of any other cured rupture. Umbilical rupture, undoubtedly when of original production, is often cured without much difficulty; but in this case the sac of cellular tissue and skin is actually thrust into the aperture like a plug, which, being more and more closely embraced by the natural disposition to contract, which the umbilical hole has in infancy, union takes place between them, and the cure is thus effected.

Occasionally it happens in all, and especially in large ruptures, that they cannot by any means be kept within the cavity of the belly, and, being thus unrestricted, go on increasing until nearly all the bowels are contained in the rupture-sac. All that can be done in such a case is to protect and support the rupture by suspensory bandages of various kinds, which may be made of some sufficiently stout material, to prevent further protrusion.

Sea-Sickness.—A correspondent of the *Lancet* gives the following lucid (?) explanation of sea-sickness:—I believe that in sea-sickness a churning motion of the blood is kept up, in the large blood-vessels going to the brain, and in the sinuses, &c., of the brain. Sometimes there is too much blood, sometimes too little, there. Confusion takes place, and sympathetic nausea and retching, &c., from irregular distribution and circulation of blood in the brain. [In all probability, the writer had suffered from sea-sickness, and his brain had been so *churned* that it had become converted into butter.]

A Course of Lectures on Practical Midwifery.

Delivered this Session at St. Bartholomew's Hospital, and revised especially for the Medical Times,

By EDWARD RIGBY, M.D.,

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery at St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

PREMATURE EXPULSION OF THE OVUM.

GENTLEMEN,—From the great variety of forms under which premature expulsion of the ovum may take place, as well as from the number of causes which may give rise to it, it becomes a matter of considerable importance. In order to facilitate a correct understanding of the subject, most of the continental writers have divided it under three heads, according to the periods when it occurs. Thus, expulsion of the ovum previous to the sixteenth week is termed *abortion*, from which time until the twenty-eighth week it is called *miscarriage*, and after that period *premature labour*.

A child may be born at a very early period of pregnancy showing distinct evidences of life, but it will not be capable of maintaining an existence apart from its mother until the last division, or, in other words, until after the twenty-eighth week. Cases, I own, have occurred of children having been reared which had been born before this period, but they are exceedingly rare, and must be looked upon as exceptions to the rule

It is not less important to distinguish abortion from miscarriage than miscarriage from premature labour; not on account of the child, because of course it cannot be saved, but in order that we may form a more correct estimate of the danger to which the mother is exposed.

Abortion is the most frequent, and fortunately also the least dangerous form of the "*Partus ante justum terminum*," because the uterine development being inconsiderable, the blood-vessels are small, and the hemorrhage seldom of any amount. On the other hand, a miscarriage is a much more serious affair; the development of the uterus and embryo are further advanced, the process is usually attended with severer suffering, greater loss, and more serious derangement of health.

You will recollect, when speaking to you of the decidua and the fœtal membranes, that I stated them to have a much feebler attachment to each other, and to the uterus, in the early weeks of pregnancy than afterwards, so that a separation can be much more easily produced at this time than at a later period; and now also that the ovum is small, a slight separation will be a much more serious injury to it than a larger one when it is more advanced.

Thus Dr. W. Hunter says, "When seven weeks are up, I know that they are near the time of trial or of blighting; when *that* happens they must miscarry, therefore that is the time for fear. I shall be sent for perhaps to a lady miscarrying about the eleventh week—it is too late to prevent it—nothing in particular can be done. I know the child is dead, and she will most likely miscarry in the twelfth week. This happens (death of the child) commonly about the eighth week or beginning of the ninth; but we are not certain to a few days. The dangerous time of blighting, then, is about the eighth week, and the miscarriage happens a little after."—(MS, Lectures).

I before mentioned to you, when speaking of the death of the fœtus, that this occurrence is not necessarily followed immediately by its expulsion, and, generally speaking, the earlier in pregnancy the embryo is destroyed, the longer is it before abortion takes place. When, however, the pregnancy has become advanced, so that the uterus has acquired considerable size, miscarriage generally follows soon after the death of the fœtus. The os uteri becomes flaccid and relaxed; it dilates somewhat; and the membranes, running into putrefaction, are no longer able to bear the weight and pressure of the liquor amnii; they, therefore, burst, the liquor amnii escapes, and expulsion follows.

In an old set of aphorisms on this subject by the celebrated Mauriceau, published in 1694, it is stated that the fœtus runs into a state of putrefaction much sooner when the violence, or other cause, which occasioned its death has also produced a rupture of the membranes. The cause of this is very evident, and it is no less plain that, under these circumstances, the fœtus will not be retained.

The causes of premature expulsion of the fœtus are numerous. I may mention, as among the most common, external violence, sudden shocks—either affecting the body; sudden alternations of heat and cold; debilitating evacuations; certain purgative medicines, which irritate the intestines, and act by the propagation of this irritation to the uterus; certain medicines which act by irritating the bladder—such as savin, cantharides, &c.; other substances which seem to act specifically on the uterus; as ergot of rye and some others. Dysentery, which some women are very liable to during pregnancy, is a frequent cause of miscarriages. The irritation of the bowels is here propagated to the uterus; I recollect one lady whom I attended, and in whom I had the utmost difficulty in preventing a miscarriage, in consequence of the severe and distressing dysentery she suffered from during her pregnancy.

There is another set of causes to which I must allude, which I shall name *internal causes*. I mean plethora, and its effects. Abortion from an overloaded state of the uterine circulation is by no means uncommon, and generally takes place at one of those periods which, in the unimpregnated state, would have been a menstrual period. A woman can often by certain symptoms recognise her menstrual periods throughout her pregnancy; and these are the times chiefly to be watched, if you suspect anything like a plethoric tendency. Plethora at these times produces a degree of uterine congestion, which may give rise to a kind of uterine apoplexy, and extravasation of blood may either destroy the child or rouse the action of the uterus to expel it without this previous effect.

There are many other causes of premature expulsion of the ovum. All the various dyscrasies of the system, which either rouse the uterus to contraction or destroy the child. Syphilis and mercurial erethism act by destroying the child. Constipation, when allowed to continue unrelieved, is a very frequent cause of abortion. A woman may produce a dangerous degree of congestion of the uterine system by too long standing, or by long continued walking exercise. I know one case of a lady who had a great dislike to children, and who endeavoured to induce abortion by continued standing. She was seized with a great desire to attend sales, &c., and would stand for hours with this intention, and nothing would induce her to sit down at evening parties, but she would stand until she was ready to drop. Of course, Gentlemen, such conduct is perfectly unjustifiable. Other diseases arising from mal-assimilation—as gout or rheumatism may produce abortion. A rheumatic gouty habit, indeed, gives rise to a very irritable state of the uterine organs, and renders it very difficult to carry the patient safely past her monthly periods.

As a general rule, Gentlemen, you must bear in mind this axiom. *The same causes which in the unimpregnated state produce derangement of menstruation and other uterine disorders, now act as so many causes of abortion.* Spasmodic affections which are common during pregnancy—such as irritation of the nerves of the face, toothache, &c.—may give rise to abortion, and it generally happens at what in the unimpregnated state would have been a menstrual period. Abortion may thus take place at the first or second period, so that the woman in many of these cases does not even know she is pregnant.

Too frequent sexual intercourse is undoubtedly not an unfrequent cause of mischief in the early months, which I need hardly say does not exist as pregnancy advances.

Abortion is observed far more frequently in the upper than in the middle and lower ranks; indeed, I may say that a fifth, or even a fourth, of our ladies of rank abort in their first pregnancies. This may easily be conceived when you recollect the life they lead: their late hours, both of rising and going to rest, the tight dressing, nourishing and stimulating food without the proportionate degree of active exercise, warm beds, hot rooms, crowded assemblies, and mental excitement—all tend to unfit them for passing through the important process of early pregnancy safely.

Abortion may be defined to be a separation of the ovum, with contraction of the uterus.

When the pain precedes the discharge, we can rarely prevent abortion from taking place; but when the discharge has come on without pain, the prognosis will be more favourable. These two symptoms, I need hardly tell you, are caused, the first by the separation of the ovum, more or less, although it may occur without; the second by contraction of the uterus. Now, when the pain precedes any external discharge, we are justified in supposing that there is a high degree of irritation set up in the uterus, which has probably arisen from extravasation of blood at the upper part of the ovum; in order to permit the escape of this, it will be necessary for the ovum to be still further separated, most likely to a considerable extent, which gives but a poor chance of the patient escaping abortion. If, on the other hand, the discharge occurs without pain, or with very little, the separation of the ovum is probably near the os uteri, where it finds a ready escape, and after the discharge of blood has relieved the uterine congestion, she may go on without expelling the contents of the uterus. I have met with numerous cases of this kind. In many the patient has experienced much relief from the discharge. She has felt cooler and lighter, and in better health altogether, and has afterwards carried the ovum to the full period.

As regards the prophylactic treatment of a patient with a tendency to abort, much may be done, perhaps even more than in the treatment of the attack itself. It is of great importance in all cases to prevent abortion, if possible; for although many fashionable women may look upon it as a matter of no consequence, still in the end they are sure to suffer from its injurious effects.

In deciding on the prophylactic treatment, a reference to the predisposing causes is absolutely necessary; but in all cases a strict attention to the removal of causes of irritation from the stomach and bowels is indispensable. Everything capable of exciting the circulating system must be strictly avoided; the diet should be light and nutritious; regular exercise—never, however, carried far enough to produce a sense of fatigue—should be taken, and every means should be used to promote a healthy state of the system generally.

The first thing, Gentlemen, for you to ascertain is, whether the system be above or below par, in point of strength or tone, since abortion may arise from two very opposite conditions. If the patient have miscarried on a former occasion, you must be careful to watch her past the period of pregnancy at which the abortion previously took place; for the uterus soon acquires a habit of contracting on its contents at a certain time. In such cases, if the patient be plethoric, venesection becomes necessary; but this must be performed with much caution. Faintness must never be induced, and sufficient blood only should be drawn to reduce the pulse in hardness After venesection, if any uterine irritability be present, opium should be administered. This, with a spare and regular diet, mild saline laxatives, regular exercise, light and loose clothing, &c., will often suffice to save the pregnancy. If, on the other hand, your patient be a weakly, delicate woman, with no stamina, wine, iron, and tonics must be given freely. I once saved a patient purely by these means, who had aborted several times previously. In a succeeding pregnancy she aborted before I could get to her, and a very serious case it proved. You thus see that, in some cases, we must adopt a treatment diametrically opposed to that required in others. In those cases which show a state of atony of the system generally, you must advise the cold hip-bath, and cold sponging, with a light nutritious diet. There is a work I should recommend to your notice very strongly; if ever you can get hold of it at an old book-stall, by all means buy it. I mean White's Observations on Lying-in Women. It contains some admirable remarks on the use of the cold bath, among other topics connected with this subject. I am in the habit of prescribing this mode of treatment very frequently, and I can, from my own experience, vouch for its beneficial effects. You have no idea how far it may be carried with benefit

when commenced early, or even before pregnancy, and carried on regularly. One patient of mine continued to bathe in the sea till January; another, a relative of my own, went on bathing every morning in the sea till the day of her labour.

In patients who have manifested a decided tendency to abort, you must not be above inquiring into the minutest particulars. Very slight causes of irritation may be sufficient. Tightness of the dress, by irritating the breasts, and preventing their development, may determine its occurrence.

In some women, as I have before told you, the uterus gets into a habit of expelling its contents prematurely, so that they never bear the child beyond a certain period. When abortion has thus become habitual, in spite of all our precautions to prevent it, the only chance will be by giving the uterus an entire rest for a considerable period. You should advise a complete separation from the husband for twelve or fourteen months, and after this you may by care enable the patient to carry her subsequent pregnancies to the full period.

Dr. Young, a former professor of midwifery at Edinburgh, used to quote a case of a patient who had miscarried thirteen times, and yet bore a child at the full time in her fourteenth pregnancy, so that we must not despair in these cases. At the same time let me beg you never to underrate the injurious effects of repeated abortions; menstrual derangements, such as dysmenorrhœa and menorrhagia are not unfrequently the results—not to mention leucorrhœa, inflammation of the cervix uteri, and disposition to scirrhus and other organic mischief.

In speaking to you of the effects of plethora in inducing abortion, there is a little quotation which I intended to have made from Dr. Dewees' writings respecting the pernicious habit of taking too much nourishment. Speaking of the sickness which occurs during early pregnancy, he says, "It certainly cannot be intended for any other purpose, since it is not only almost universal, but highly important when it occurs, as it would seem to add much to the security of the fœtus; for it is a remark as familiar as it is well grounded, that very sick women rarely miscarry; while, on the contrary, women of very full habits are disposed to abortion, if exempt from this severe, but as it would seem important, process."

You see, therefore, that, in these cases, you must act carefully. "We might often prevent abortion," says Baudelocque, "if we were perfectly acquainted with its cause, even when the labour is already begun. A very plethoric woman felt the pains of childbirth towards the seventh month of her pregnancy, and the labour was very far advanced when I was called to her assistance, since the os uteri was then larger than a half-crown; two little bleedings restored her calm so much, that the next day the orifice in question was closed again, and the woman went the usual time. Food of easy digestion prudently administered, quieted a labour not less advanced in another woman, where it was suspected to be the consequence of total privation of every species of nourishment for several successive days. Delivery did not take place for two months and a half afterwards, and at the full time. Emollient glysters and a very gentle cathartic procured the same advantage in a third woman, in whom labour pains came on between the sixth and seventh months of pregnancy, after a colic of several days' continuance, accompanied with diarrhœa and tenesmus." Here, then, we have three cases related arising from three very different causes, and yet by three different modes of treatment they were all conducted to a satisfactory termination. To resume. If the system be plethoric you must bleed sparingly, but you must recollect that great caution is here requisite, as sometimes the abstraction of very little blood will in these cases produce powerful effects. Often as much blood may be lost by hemorrhage without danger as would produce serious faintness, if removed by bleeding. The patient must of course be ordered to bed; the feather-bed being removed from the mattrass, and cloths wetted with cold water, or vinegar and water, should be applied to the perineum and mons veneris. I am no friend of the application of ice in these cases, as I have seen it do harm by causing so much collapse as even to require warmth and stimuli to remove it. As soon as you have reduced the power of the circulation, or if the patient be not plethoric, immediately, you must give a full dose of opium. I prefer the liquor opii sedativus or morphine, or you may administer a clyster containing a full dose of opium in a small quantity of starch. If the flooding be at all profuse you may be convinced that separation of the ovum has taken place to a considerable extent, so far, indeed, that reunion cannot be expected, and you must, therefore, turn your attention to its expulsion with as little danger to the mother as possible.

Clinical Lecture on Typhus Fever.

By Dr. Corrigan.

Delivered at the Hardwicke Hospital, Dublin.

Typhus not a Disease of Structure; Importance of this in Practice; Typhus analytically considered; Most important Phenomenon a Lesion of Circulation; Administration of Wine; Objects of it; Rules for it; Injections of Æther; Flying Blisters, &c.

There are at present in the house, Gentlemen, a good many cases of fever, to the consideration of which I shall devote a lecture or two; and I may observe that this subject, like that of inflammation, is perhaps, of all those connected with our profession, one of the most puzzling to the beginner.

In order to lessen some of the difficulty, I mean, in investigating the subject, to adopt the analytical mode, that is, to endeavour to divide fever into the lesions which constitute it, and to take up the consideration of each of these in the order of its relative importance, in the production or rather constitution, of the disease. The type of fever, which prevails at present, may properly and characteristically be called *low typhus*. And here the question which naturally suggests itself is—What is typhus? But in order to arrive at the answer, it is first necessary to know what it is not. And I shall here read the case of a girl admitted to the hospital a few days ago, which may assist in enabling us to reach this point.

Mary Redmond, aged twenty-five, twelve days ill; had at first complained merely of very slight headache. Her body on admission was thickly covered with petechiæ and maculæ; pulse exceedingly compressible. Her intellect, however, was unclouded, though dull; the abdomen soft; respiration hurried; but with no evidence of disease in the lungs. In five days after she died, and on examination after death there was found no trace of morbid alteration in any organ of the body, there being an accumulation merely of a quantity of mucus in the bronchial tubes, which is always found to accompany the last struggles, not alone in this, but in most other diseases. The digestive organs presented not the slightest trace of disease; neither the mucous membrane of the small or large intestine had the least appearance of that disease—follicular enteritis—to which the French attach so much importance. The case was, in fact, one of pure typhus, with no local lesion whatsoever.

One point, then, is clearly established by this case: it teaches us that typhus fever is not a local disease. No alteration of structure is necessary to its production. There is here not one trace of any local lesion, which shows clearly that the disease before us consists solely of functional lesions—a fact which is taught to us by the pathology of this single case.

In comparing facts or arriving at conclusions, it is necessary sometimes to accumulate a great number of instances from which to draw an inference; but sometimes a single instance is of more value than the large number, on account of the evidence it affords. It might happen that twenty, thirty, forty, cases of fever would be accompanied with follicular enteritis, yet it would still remain to be proved, whether the intestinal disease arose in the course of the fever, or was the cause of it. If, as I before observed, in a single case, like that just read to you, we find on examination after death no structural lesion whatever, though it may have occurred in other cases, even in a great many, it must in them be looked on as accidental. The lesson which this case teaches us is the first step in the study of the disease before us—a lesson useful not alone as regards the pathology of the disease, but also to the practical physician.

If, in treating a local disease, you find symptoms indicative of approaching death, with, in fact, hardly any prospect of recovery, as in a case, for example, of cerebritis, pneumonia, &c., you might abandon such a case as hopeless; but this should not be as regards typhus fever: there being here no structural disease explains how it is that often, under apparently the most hopeless circumstances, the patient rallies. A person, at the very threshold of death—the action of the heart having almost ceased—in fact, all but dead, is found, in twenty-four hours, totally out of danger. Such can never occur in structural or local disease, but very frequently does in typhus fever. And from it you learn not only a confirmation of what is told by the case before you, but also that, while there is breath in your patient, he is not to be finally deserted—not while there is even a single respiration—until the mucus has accumulated to such an extent as to fill up the larynx itself. This, even as a mere abstract pathological fact, thus comes to be of the utmost practical importance.

Having now determined what fever is not, we come to consider what the disease really is, in doing which I shall endeavour to keep strictly within the bounds of clinical medicine, and would warn you here against theories, not that I would have you refrain from reading works on theory of medicine, for sound theory and good practice are very closely allied, but, for the time, get rid of all theories and hypotheses, and stand at the bedside of a patient in typhus, carrying with you the information just now obtained, bearing in mind that you have no structural lesion to deal with, and that your patient, as I have said, from an apparently hopeless state, may be free from danger in twenty-four hours. What, then, is the disease? Is it a disease of the brain? Certainly not; the post-mortem examination reveals no trace of disease there; and the patient during life was rational, the intellect was unclouded; she was capable of answering correctly questions put to her. Is it disease of the lungs? Assuredly not; for there were here neither the post-mortem evidences of such, nor the stethoscopic evidences during life. It is decidedly not disease of the digestive organs, or some trace of it would be found at the autopsy. Thus, then, you see distinctly what the disease is not.

Let us, still carrying on this mode of unprejudiced examination, turn to the circulating system. We find the pulse exceedingly soft, hardly capable of bearing the slightest pressure. So far we derive information as regards one part of the circulating system; but, in practical medicine, never look upon that system as a single one, but consisting of two important parts; the one comprised by the heart, arteries, and larger veins; but which is the minor system as regards its importance to life, for we know that many living beings are unprovided with a heart, which, after all, may be looked on as a kind of pump which receives the blood on one side and enables it to obtain renewed vitality, while, from the other side, it is sent through the several large tubes to the different parts of the body. The second division of the circulating system is that really of most importance to the physician, and to which sufficient attention is not at all paid in reference to its function in the living body. This is the system with which we have to deal here, and upon which life very often depends. Look to that system in a case of typhus, and you find, first, that all those parts, naturally of a florid colour, from the quantity of blood contained in them, now assume a dark, lurid hue—the cheeks for instance. The darkness tells us here what the philosophical experiments of Hunter told in their way, that the circulation is not carried on with vigour; and in proportion as this system becomes enfeebled, do we collect the signs which are to guide us in treatment. You see the conjunctival vessels engorged, and if you pass from these and the cheeks to the surface of the body generally you there observe over it a mottled hue, and you find it covered with maculæ caused by the distension of the smaller vessels with blood; these latter sometimes giving way, so as to permit effusion into the tissue of the skin constituting petechiæ. It is useful and easy to distinguish between these

two, the pure distension constituting the maculæ, and the extravasation producing petechiæ. Press upon the discoloured spot with the finger, and if it be only distension of the vessels or a macula, the colour disappears to return again; while if it be blood effused into the subcutaneous tissue or a petechia, it remains unaffected by pressure. And here I may notice a practical observation, to which these maculæ have given rise, viz., that in proportion to their darkness is the severity of the disease, a fact which is also in accordance with the views I have here adopted, that in proportion as the capillary system becomes enfeebled, the case also is low and dangerous.

If we pass now from the mere examination of the surface, and turn to the back, and most depending portions of the body, what do we find? that whenever obstruction to the circulation, even in the slightest degree exists, from the mere weight of the body on the skin, the capillaries have become so enfeebled, so utterly incapable of carrying on the circulation, that gangrene is the consequence. The microscope shows us that when the capillaries of a part are so enfeebled by constant irritation as to be unable to carry on the circulation, gangrene takes place, which gangrene is nothing more nor less than the stoppage of the circulation in those capillaries.

Hence it is that in practice our attention is always directed to those parts which also furnish an indication of the severity of the disease, and the moment this distension shows itself we meet it by local stimulants. Here then is another proof that debility is the great phenomenon with which we have to contend. Passing now from these evidences of vascular derangement manifested by the conjunctiva, cheeks, surfaces, &c., if we look to the urine, we find it often presenting a corresponding darkness of colour; it is muddy, albuminous, and of low specific gravity, showing that there is also some affection of the capillary system of the kidneys, permitting an excretion of parts of the serum and colouring matter of the blood with which they are supplied.

We thus very often derive information from an examination of the urine, for though in some of the very worst forms of fever the kidneys are unaffected, still they as frequently are disordered.

If, in addition to the dark colour, the urine is muddy, and does not deposit a sediment, and the fluid is found to be albuminous when heated, it adds much to the severity of the case.

Having carried out these views so far, I must remind you that the capillary system is not confined to those parts which are visible to the eye, or appreciable to the touch, but that as a whole it extends to all the internal organs, and that we have a right to assume that there is a condition of their capillary vessels similar to that which we find on the surface, and why? The urine tells you that there is the same tendency in the kidneys to the escape of blood from them as in the vessels of the skin, which give rise to the petechiæ. As the fever advances, therefore, the capillaries of the lung take on a condition, not such as occurs in common pneumonia, but a state of hypostatic congestion.

We have a right to look upon the capillary system throughout the body as a whole. Suppose it were possible to reverse the organs, and that the external surface became the internal, I can have no doubt but that the internal capillaries would exhibit conditions precisely similar to those of the skin.

Get rid of all hypotheses, analyse the disease as I have told you, and you must arive at the conviction that it principally consists in a want of tone in the capillary system generally, not in a lesion of any one particular organ; and being convinced of the existence of this general lesion, there is little difficulty in accounting for the great debility and symptoms of prostration under which your patient labours.

With these views of the nature of typhus fever, you can now understand the apparent anomalies that belong to the disease. A person may die in typhus fever after eight or nine days' illness, with the intellect remaining perfectly unclouded, the tongue moist, and the evacuations natural.

I remember that, some time ago, several patients were brought to the hospital suffering under typhus fever, from having been exposed to wet, cold, and hardship, on board the deck of a steam-packet; these people lay in their beds in a listless condition. When spoken to they answered rationally. The tongue was natural, and the pulse not more than 70 or 80, and yet the majority died.

The patient dies then of the lesion of the function of circulation. I wish to fix your mind's eye on what really is the phenomenon we have to deal with.

I shall follow up the same analytical course in speaking of treatment, and combine, as it were, with each particular lesion the treatment adapted to it.

In connection with that which we are now considering, naturally comes the administration of wine, which seems involved in so much difficulty, that if you take up the different writings on the subject, you too often rise from their perusal bewildered by the directions you receive. You are told to avoid it in delirium, and yet that wine may be advantageous in some cases: that it may be given if the tongue is moist, or occasionally with a dry tongue when it is becoming moist, and so on; and in the end you turn down the leaf, without any decisive ideas on the subject.

Instead of attempting to reconcile these contradictory statements, or of enumerating the number of functional lesions in which wine may be given, let us stand by the bedside, and ask ourselves what do we give wine for? Is it for lesion of the nervous system? In many cases the nervous system, even the brain itself, is undisturbed. We don't give it for the affection of the lungs or of the intestinal mucous membrane, should such exist. For what, then, do we give it—what induces us to administer it? It is for this one lesion, the lesion of the circulating function, indicated by the condition of the heart and larger vessels, and the pulse at the wrist, on the one hand; the state of the skin and the capillaries of the conjunctiva on the other, &c. Wine is a remedy to which we attach great value in meeting the most important phenomena accompanying our present type of fever. For the support, then, of the cardiac circulation, and the still more important one, that of the capillaries, keeping in view the state of the pulse, and the skin in reference to the maculæ and petechiæ, we give wine. Whether there be delirium or not, whether the tongue be dry or moist, whether the abdomen be soft or tympanitic, it matters not what the state of the other functions is, if the capillaries are in a state to require it, the wine must be given. You are not, I repeat, to mind whether your patient is delirious or not; you are to examine the state of the function of circulation, and to adapt your remedies to it.

It may be combined with the administration of mercury, or with the use of cold or hot applications adapted to the particular lesions requiring them, but give wine for that one lesion, and no other. You will see wine given with advantage where the vessels of the conjunctiva are distended, and they contract for the very same reason that under its use the maculæ on the skin grow pale, the darker ones grow florid, and the petechiæ disappear. Wine as an internal remedy may be considered to act upon the capillary system as camphorated spirit does applied externally. It will sometimes happen that your patient is so debilitated as to be unable to swallow, and you are obliged to raise him up by the head and shoulders, in which erect position the fluid will reach the stomach principally by its own gravity, though he has not sufficient power to swallow it in a lying position. In some of the very worst forms of fever the powers of life have been supported, the function of circulation has been kept from sinking, by the administration of brandy and æther in injections when the patient was dying, when he was on the very threshold of death, and where there was no one cause for it upon which you could lay your hand—let people reason and write as they like—except that which I have dwelt upon.

Another practice of considerable power is the application of stimulants to the skin, for the purpose of giving tone to the capillaries. Blisters, hot turpentine, sinapisms, &c. What do we apply these remedies for? Not for the purpose of counter-irritation, for there is no disease of the internal organs—you find none after death. Two, four, or eight blisters are given to the nurse, not, as I say, for the purpose of counter-irritation, but viewing the capillary system as a whole, they are applied to different parts of the surface every four or six hours, and the effect is carried to the capillaries of the internal organs—in fact to those over the whole body.

The support of this peculiar function of circulation is your object all through. In some cases of maculated fever four or six ounces of wine in the day may be sufficient, while in others thirty-six may be necessary; there is no rule for its administration. A curious fact connected with it, too, is that the lower classes very often require more wine than the upper; the explanation of which, perhaps, is this, that when a very bad case shows itself, such for instance as those on board the steamer that I mentioned a while ago, the debility is so great, that stimulants are required for a longer time, and in greater quantity, than in the upper classes, who are in general not subjected to a continuance of the same debilitating causes acting upon the circulating functions.

ORIGINAL CONTRIBUTIONS.

NOTICES OF BRAZILIAN MEDICAL JOURNALISM.

By Richard de Gumbleton Daunt, Esq., M.D. (Edinburgh),
Member of the Faculty of Physicians of Rio de Janeiro, and Member of, and late honorary Secretary to the Parisian Medical Society.

Pernambuco, Bahia, and Rio de Janeiro all have their separate periodical medical publications, the latter city possesses two journals, one the organ of the Academy of Medicine, the other an independent publication, to which, the contributors are chiefly the younger Professors of the School of Medicine, or the aspirants to future vacant chairs in that body. It appears monthly under the title of the "Archivo Medico Brasileiro," on good paper, and contains from twenty-four to thirty-two pages of royal octavo, the price being sixteen shillings and sixpence annually. It is conducted with some activity, and occasionally a good article appears: the lower third of the first pages is occupied by a feuilleton, in imitation of the "Gazette Medicale" of Paris. In this various questions connected with medical politics, the passing events which interest the dignity or welfare of the profession or the public health, are treated of in the usual style of feuilleton writing and with some ability, and always in a tone of high moral professional feeling. In the first number of the second volume, (that for September, 1845), there does not appear one original article worthy of notice; in the second number, however, the editors have been more happy, and I shall proceed to notice the several original communications seriatim. The number opens with a popular article on vaccination by Dr. Feital, descriptive of its uses, &c., and some notes of its early history, it contains nothing new, but this is one of the subjects of which the truths cannot be too assiduously brought before the public. The second article is a resumé of the actual state of our knowledge as to the causes giving rise to Thermal Springs, and is by Dr. Marinho. The third is an eloquent and energetic exposition, (also ad vulgum) of the dreadful consequences of interment within churches and while various hygienic truths are forcibly inculcated, the writers, Drs Costa and Oliveira, severely criticise the conduct of those who from motives of interest make a tool of the superstition of the people to create an opposition to the formation of extra mural cemeteries. An article by Dr. Guimarvas follows this, on the use of fomentations with mercurial ointment in Peritonitis, and notes of various cases of *traumatic* Peritonitis cured by antiphlogistic means in the Rio hospital. Dr. Marinho also publishes the first of a series of lectures on climate in relation to Thoracic disease, it is, however, occupied with purely elementary notions as to what constitutes climate in an astronomical sense, and does not touch upon geographical climates. We then find the usual well drawn up statistical table of the mortality for the preceding month in the city of Rio de Janeiro by the editor in chief, Dr. Lupa. The remaining article,

and one which I shall proceed to translate at length, is by Dr. Cyprian J. de Carvalho, an army surgeon, and was called forth by the publication of a case of prolonged sleep or coma, extracted from a German Journal, the opinions of the narrator on the physiological state of the subject of the case being combated by Dr. de C. it will serve as a specimen of Brazilian medical criticism.

Translation.—" In order that the fact extracted from the 'Medecinische Zeitung,' in the last number of the 'Archivo Medico Brasileiro,' may not remain for any length of time unique and isolated we hasten to publish the following, which we had occasion to observe twice during the period of our military medical service in the province of San Pedro do Rio Grande do Sul. Seven leagues, more or less, from the town of Bagé, resides the subject of the following case. This female is from thirty-two to thirty-four years of age, never was attacked by any illness, (unless the phenomenon we are about to relate may be considered one), is of delicate constitution, thin and pallid. This pallidness and emaciation, however, only commenced five or six years back; previous to this date she was somewhat stout, and her cheeks presented a healthy color; she was married fourteen years ago, and has a healthy daughter of eleven or twelve years of age. She had the misfortune to be abandoned by her husband about one year after the marriage, and from the affliction thus caused, resulted the following phenomenon, viz.: she is subject at irregular intervals to comatose attacks, which seize her suddenly either by day or night, and endure one, two, and even five days, in which time she neither drinks, eats, nor executes the slightest movement: there are moments, though rarely, when she appears to rouse herself, since she changes her position, and when spoken to gives evidences that she hears, procuring with her hand the person addressing her, but answers nothing, and returns to her former comatose state. On the occasion of our first interview with this patient, (we were then in the company of Dr. M. F. Pereira de Carvalho,) we found her in her usual comatose attack, and examined her leisurely. She was tranquil, the respiration very regular and free, the pulse though weak and depressed, was very perceptible and the pulsation regular; the extremities were flexible, the temperature of surface natural, the palpebræ closed, and the globe of the eye turned upwards, the mouth humid and firmly closed; no casual spectator would have hesitated to say that she was in a physiological sleep—a sleep reparative of the forces. She had been already three days in this state, when at night one of the bands (the head quarters of the army being close to the house) had scarcely commenced to play, when she awoke, sat upright, and with wondering features examined all around her, saluted us, rose and went to the window in order to hear the music better, and passed the remainder of the night in agreeable conversation. The following day the army continued its march, and we lost sight of the case. About one year after this we again saw this female; but now, music produced an effect quite contrary. The army encamped a short distance from the house, and she saw it arrive. By chance the band commenced to play, and the coma seized her almost as soon as the first sound struck her ears; we arrived in a little while at the house, and found her in this state; but on this occasion it lasted but a short time, and was of slight intensity, for at each instant she seized our hand and placed it on her stomach as if accusing some painful sensation at this part; still she was speechless, and on recovery had no recollection that she had been spoken to. We then inquired how she felt, and were answered *that she was much fatigued, and that she awoke thus when she slept much; but that she wondered what kind of sleep this could be, seeing that after sleeping two or three days, as her friends told her, she often awoke still overpowered with sleep; that she presumed it to be some disease, but as she had no pain and ate well, she concerned herself little about it.* We examined her pulse and found it identical with what has been observed in this state of lethargy. We learnt that in the commencement, the simple application of burnt feathers was sufficient to remove this state; now, nothing can effect this but time alone.

"When reading the case reported by Professor d'Outrepont, the above case instantly occurred to our memory, and which, while presenting so many points of contact with his, we never considered as being a state of sleep; and much less as healthy, the female who was the subject of it, though both the peculiar state and the patients, are thus spoken of by Professor d'Outrepont; various doubts arose in our mind on reading the case referred to, which we shall now present, leaving to those better informed the solution of the question.

"The principle characteristic signs of the peculiar condition of the organism to which the name of sleep has been given, are two in number. 1. The cessation of the exercise of the intelligence and of all voluntary acts, or rather the loss of the power of the will over those acts, which may yet be performed while in this state. 2. Reparation of the energies of the nervous system, and fitness for entering on the usual business of life on awaking. These we believe to be the two specific signs of a physiological or reparative sleep. Both, however, must be united to qualify any such state as real sleep.

"This being established, let us analyse the case of Professor d'Outrepont, and let us inquire if such a state as there described, merits the name of sleep.

"In both his case and ours there is entire loss of intelligence and of voluntary motion; fatigue and loss of strength on awaking. In both cases there is then wanting the second and most characteristic signal, that without which, no suspension of cerebral action can be considered as sleep. 'It is,' says Professor Adelon, 'because this last character has been neglected, that so often various morbid states have been confounded with sleep, which alone have in common with it, the loss of all consciousness of the ego.' Thus it has happened to the narrator of the German case; at least we frankly confess, that our intellect is unwilling to accept these phenomena as being the physiological states, as Professor d'Outrepont does by inference, in heading his case, "Sleep of from two to seven days in a *healthy* female." How can we regard as *healthy* a female, the subject of a fact so contrary to the facts of an ordinary physiological state? a phenomenon whose accompaniment is the withering of the individual who presents it, as we saw in the subject of our own case, *we* cannot so think." * *

Two similar paragraphs close the communication, which as they contain nothing different in style to the preceding, or important in matter, I do not think it necessary to translate. This journal cannot fail of effecting some good, as it is extensively read in the interior, and were the selections from the European Journals well made, would be still more serviceable. At present there is a marked want of contributions from the provincial practitioners, among whom, especially in the southern provinces, are many men of much greater natural ability than are usually found in Rio, either city or province. It is to be hoped that the example of their younger colleagues in the metropolis of the empire, may serve as a stimulus to this class. Considering, however, the early efforts of English medical periodical literature, and the comparatively recent date at which it assumed a creditable form, the present medical journalism of Brazil may justly be regarded as far more creditable to the country than *was* that of England.

A series of articles, similiar in nature to the present, will however, place the readers of the Medical Times in a position to form for themselves opinions on this point.

City of Campinos, Province of San Paulo,
Brazil, December, 1845.

ON THE PATHOLOGY OF THE BLOOD.

By John Nicholson, M.R.C.S., Eng.
Surgeon to the Hexham Dispensary.

Introduction.

General Remarks on its Constitution.—The blood is, from its aspect, apt to be viewed as a fluid holding in suspension a number of ingredients, without order, and wanting in proportional quantities. That the serum of one man may contain more *albumen* than that of another; or, that the *clot* may be larger in one case than in another, we readily grant; but, in the same individual the elements exist unquestionably in "fixed proportions." All things else in nature point to this law; and it is scarcely probable that the blood should constitute an exception. If there is no order in its constitution, how are its molecular actions effected, and by what means does it preserve its characters? It possesses in health a specific heat; and why should it not have a specific quantity of each element?

Assuming, therefore, a certain proportion of each ingredient to exist in the blood of every individual, any derangement must, of necessity, cause a corresponding change in the general system. For illustration, let us suppose there were a diminution of the soda which holds the albumen in solution, the consequence would be precipitation of that animal principle; or, at any rate, it would not be able to flow with sufficient facility through the channels destined for its transmission.

Similar would be the result if any acid came in contact with the alkaline base, by which the albumen is dissolved.

On the other hand, suppose the salts of the blood to be materially increased in quantity, the formation of the globules would probably be arrested; or, if formed, they would be rendered imperfect.

If the red particles were much augmented in number, there would be an activity in the system beyond what is necessary to ensure healthy nutrition; and so tend to establish plethora and its dangerous consequences.

But by an excess of serous fluid there would be the very converse of that which a preponderance of globules would develope.

A large proportion of water enters into the composition of the serum—almost nine parts in ten. Suppose, then, it be decreased or diminished, what would result? The former would impoverish the blood and weaken, to some extent, that necessary and vital affinity which holds the elements together; the latter would cause it to be viscid, impede its circulation, and equally interfere with its molecular action.

It is true that we have spoken of the above changes as a mere matter of theory, founded on the principles which physiology and organic chemistry furnish; but the following pages will contain facts to establish their correctness, as well as to prove that the state of the blood bears an important part in the origin and course of disease.

History of Opinions.—From the time of Esculapius to that of Hippocrates, little can be said of the opinions which practitioners held of the nature of disease. With the latter author originated the idea, that derangement of the humours of the body is the starting point of every malady. Galen embraced this theory, and added much by his subtle reasoning and acute observation.

The humoral pathology acknowledges Hippocrates as its father; but Galen was the great means of its celebrity and prolonged reception. His writings suited the taste of the Arabian philosophers, and soon placed these doctrines beyond dispute in that school. Thus we find, by reference to history, that *Serapion, Alkhendi, Rhazes,* and *Avicenna,* were all supporters of the humoral theory; or, that the blood is the seat of disease, as propounded by Hippocrates.

The humoral pathology continued to have full possession of the mind for many centuries: and every succeeding age appeared rather to bring it new strength and support. As Bostock* well remarks "even after the chemists had subverted most of Galen's dogmas, and had produced a total revolution in medical practice, the blood was still regarded as the origin of diseases; and they were ascribed to an acid, an alkaline, a watery, a saline, a putrid, or some other imaginary condition of the fluids." The mathematical physiology also admitted the blood to be the primary cause and seat of disease. Philosophers of this school viewed the particles of the blood as capable of undergoing some change in their physical quali-

*Physiology, page 299.

ties—as in weight, size, or viscidity; by which they thought its circulation would be arrested or impeded.

It is worthy of mention that *Sylvius* professor of Medicine at Leyden, and *Willis* and *Sydenham* of our own country, did not forget the importance of the blood in the morbid conditions of the body. *Sydenham*, however, did not trammel himself, by any theory: but carefully recognised facts as nature placed them before him.

The writings of Baglivi, of Cullen, and of others, caused the state of the blood in disease to be entirely neglected. Hence, arose the opinion, that every complaint must be the consequence of some change in the solid organs. These doctrines, like those of the humoral pathology before them, began to be too exclusively received: and until within the last fifteen years put all consideration of the state of the blood in disease out of the question. Since then, nevertheless, pathology has become so much an object of practical research that exclusive doctrines no longer exercise a tyrannical influence over the mind; because, facts carefully observed, only are received as worthy of credence, and future application. And, in proportion as, the speculative philosophy, has given way to the introduction of recorded observations, so have the doctrines of opposite schools been amalgamated. Physicians of the present day readily acknowledge solids and fluids to be both implicated in the destructive process of morbid action.

The most logical deduction of our own time, is that the solids and the blood are the two bases—the two supports of disease—inseparable elements, —alternately the cause and effect of their natural change.—The solids are but the products of the blood; and, the other humors of the body the result of the combined action of the two.

Modes in which the blood may be rendered impure.—II. That the *blood must necessarily be affected both in a primary and secondary manner* is readily perceived, if we remember that it is the internal source of nutrition, reproduction and animal temperature.

There are many circumstances which will interfere with the discharge of any one of these important functions, and thereby produce more or less physical derangement in the organ to which the duty is entrusted. If for example, the kidney is in a morbid condition, to such an extent as to interfere materially with its purifying function, the blood becomes altered in its constitution; and fatal consequences are too often the result. In like manner the blood becomes impregnated with certain principles foreign to its natural composition, when the liver is the seat of extensive disease.

The large class of complaints expressed by the generic term "inflammation" affords a striking proof of this position; and seldom, indeed, is any accustomed discharge suddenly arrested, or the circulation in a limb cut off without a very manifest effect being consecutively observed.

Inordinate secretion or excretion occasions an alteration in the relative qualities of its proximate elements, equally obvious, as the action of diuretics, or hydrocathartics sufficiently demonstrates.

The *constitution of the blood* also *depends*, in some measure, *on the metamorphosis* of tissues; for the composition of the secretions collectively is equivalent to the elements. Any circumstance which interferes with the constant and necessary change among the particles, constituting the solid organs of the animal body, must without doubt, alter the physical condition of the blood. The secretion of bile is one mode, by which *carbon* is carried from the system; and the kidneys remove superfluous *nitrogen*. The perspiration, saliva, and other products of the glandular system, act an important part in disposing of the elements of the blood—at the same time that they have other grand offices in the economy. In short life is the result of tissual metamorphosis—and the blood is the principal medium through which it is effected.

Substances taken into the body must also bear a fixed relation to the blood as well as to the secretions.

Articles of food must contain the elements necessary to carry on combustion in the lungs, for the production of animal temperature; and on the other hand, elements which supply the place of those particles constantly rendered of no further use in organic structure. If an animal be fed on substances abounding in rich nutriment, the result is, that the system becomes in proportion surcharged; but, if the food contain only a small share of nutritive matter—too little to meet the demands of the economy—atrophy of the organs, and poverty of the blood will be the consequence.

There is a variety of other facts which demonstrate the blood to be the *first* seat of disease. If we inject a noxious substance into the circulation peculiar manifestations result. Thus take alcohol for this experiment; and intoxication is produced: or a solution of strychnia and fatal spasm is the consequence. In these cases the foreign matter is mixed with the blood, and, unquestionably, occasions a change in its composition, as well as in its properties.

It is a vital and organised fluid, and must, of necessity, be affected by matters inimical to health and life, because it constitutes an important and working part of the entire economy.

It would be unreasonable to conclude that the blood is not the primary seat of change not only in these cases, but in the following striking experiment performed by *M. Leuret* on horses.

He injected the blood, taken from an animal labouring under decided "*charbon,*" into the circulating system of other horses, and invariably did he observe the same disease to be formed.

The observations of *M. M. Trousseau* and *Dupuy* are in confirmation of his statement. Analogous in principle to the experiments of *Leuret*, is the exploded practice of inoculation for *small-pox*, and the more recent discovery of *Jenner* for the prevention of the more dreaded form of that devastating malady.

A PRIZE ESSAY ON PURULENT ABSORPTION.

Communicated to the MEDICAL TIMES by THOMAS OTTREY RAYNER, M.D., F.S.A., &c.

(Continued from page 475.)

In what part of the vascular system does the formation of consecutive abscesses commence? what tissue is it that first suffers from the irritating influence of the pus? I can scarcely hope that the answer I shall make to this interesting question will be deemed satisfactory by others, though, I confess, it apppears sufficiently so to me.

It will be necessary, in the first place, to give a brief account of the phenomena of the capillary circulation, as observed by recent physiologists. The blood in its passage through both the arteries and veins is influenced by the law, that the current of a fluid moving forcibly through a tube is much more rapid in the centre or axis of the stream than at the circumference, where it is in contact with the walls of the tube. By virtue of a vital attraction, which exists between the red corpuscles of the blood, these are kept together in the centre of the stream, while a similar attraction, on the other hand, between the walls of the vessels and the colourless corpuscles, retains the latter bodies at the circumference of the stream, their motion being in consequence much slower than that of the red corpuscles; nevertheless, the force of the current in the arteries is so great that they are often hurried along with much velocity, while in the veins, in consequence of the larger size of these vessels, the current becomes so slow that the colourless corpuscles accumulate in considerable numbers at the circumference of the stream, so as sometimes to assume the appearance of a row of epithelial scales lining the tube.

These facts lead me to believe that the inflammation caused by pus in the blood commences by disturbance of the circulation through the *capillary veins*.

1, Because the solid part of pus is composed of round and compact granules, without the ductility of the blood corpuscles, or their facility in sliding over one another, and destitute of the vital attraction for one another which keeps the blood corpuscles in the centre of the stream. Now it is obviously very possible that, notwithstanding these wants, the force of the arterial current may be sufficient to carry the pus corpuscles through the arterial capillaries in the same way as the colourless corpuscles are observed to be sometimes carried, while the same force may, in the veins, be insufficient to produce that effect, the natural accumulation of the colourless corpuscles furnishing at the same time an additional impediment; they may, therefore, accumulate in the veins, and cause stagnation of the blood, and inflammation consequent upon the interruption of the *numerous and important functions* of the *venous capillaries*, which such an obstruction to the free passage of the blood through them must necessarily entail.

2. From the observation of Dance, mentioned in a former page, that upon cutting into a portion of lung, in the first stage of the inflammation that precedes the formation of an abscess, it is common to find one or more "veinules" filled with pus, I incline to the belief that the pus here referred to must have accumulated in the veinules in the manner explained in the preceding paragraph; though possibly it may have been increased in quantity so as to become visible to the naked eye, by inflammation and suppuration in the interior of the veinule itself.

3. The opinion is strengthened by the following experiment, which was performed repeatedly by Cruveilhier. He introduced a small piece of wood into the femoral vein of a dog, and passed it down as far as the hollow of the ham. The animal died on the sixth day, suffering great oppression; the whole inferior extremity was infiltrated, and all the veins and veinules injected with pus. A section of the muscles discovered little purulent points, which proved to be small veins distended with pus, the muscular tissue around them being red and softened, and presenting the same appearance as a lung in the first stage of the formation of an abscess. I confess that this experiment does not appear to me to prove so decisively that the capillary veins are the primary seats of the inflammation caused by the presence of pus in the blood, as it does to its learned author, because it is reasonable to suppose that the inflammation would propagate itself along the lining membrane of the veins, originating with that caused in the main trunk by the piece of wood. It is, nevertheless, together with the previous consideration, strongly confirmatory of the view I am advocating.

But is the rapid formation of abscesses to be atributed only to the mechanical obstruction and irritation caused by the pus in its passage through the capillaries? Or has the pus any quality which determines the inflammation to the effusion of more pus? The question is one of the highest interest and importance; but I am not in the possession of facts enough to enable me to answer it definitively. The following are the considerations which appear to me to bear upon it:—

1. The point established by recent pathologists, that inflammation is a process which differs essentially in its course and its results, according to the tissue in which it is developed, and the causes by which it is excited, now the termination in the effusion of pus, of the inflammation caused by pus, with equal or nearly equal rapidity in all the tissues, seems to indicate that a specific influence is exerted.

2. The difficulty with which pus, especially the solid part of it, is removed by the absorbents, and the tendency which an abscess, once formed, has to increase in size till it finds an outlet externally, favour the same view.

3. The fact that phlebitis is often determined by some epidemic influence of a specific kind, analogous to that by which erysipelas and puerperal fever are produced; this has been noticed by a number of different authors. It was remarked by Dance, that the greater number of the cases recorded in his paper on phlebitis in the Arch. Gen., vol. xix, occurred in the year 1828; three especially of uterine phlebitis within a few days of one another; the first on January 8th; the second, February 14th; the third, February 12th; in all these the accouchement had been natural. Two others of phlebitis from

venesection, commenced, one on May 17th, the other June 2nd, of the same year.

The three cases observed by Mr. Arnott himself, which are recorded in his paper on phlebitis in the Med. Chir. Trans., commenced, the first on November 1st, 1826; the second, January 1st; the third, January 3rd, 1827. It is reasonable to conclude that the pus, in cases like these, must act in a specific manner. On the other hand, the minute globules of mercury, which result from the injection of that metal into veins, always give rise to the formation of abscesses wherever they happen to be arrested, with as much or even greater rapidity than pus itself; and this occurs not only in the lungs, where the air might be supposed to exert its known influence in determining suppuration, but also in the liver and other organs, where the access of air is impossible. It must be recollected, however, that the result depends much on the intensity of an inflammation in all tissues, and that this must be greatly increased by the high specific gravity of the mercurial globule. To obviate this objection I performed the following experiment.

Exp. 6.—A scruple of wheat starch, suspended in an ounce of water, was thrown into the crural vein of a large dog; he vomited immediately after the operation, and had some dyspnœa, but soon recovered and appeared perfectly well. On the seventh day a drachm of wheat starch, suspended in an ounce of water, was injected into the crural of the opposite leg; considerable dyspnœa followed, but no other apparent ill consequence. Six days afterwards he was poisoned with prussic acid.

Post-Mortem Examination.—All the viscera were quite healthy with the exception of some scattered patches of emphysema of the lungs. The microscope detected a few starch globules in the blood.

Exp. 7.—A scruple of starch, suspended in two drachms of water, was injected into the crural of a small dog; the operation caused immediate howling and great dyspnœa, followed by stupor—the animal appearing to labour under great oppression of the brain. He recovered in about half an hour, and continued well for two days, except that he was rather more dull than usual. On the third day thirty grains of starch, suspended in about three drachms of water, were thrown into the opposite crural vein; violent dyspnœa supervened as before, and terminated in about two minutes in the death of the animal.

Post-Mortem Examination.—All the viscera healthy, with the exception, that a single patch of starch surrounded by a slight ecchymosis was found near the surface of the lower lobe of the left lung. The lungs were also extensively emphysematous. The great veins and right cavities of the heart were gorged with blood. Pulmonary artery quite empty. I have performed this experiment in three other instances, but every one in which an attempt was made to approximate the consistence of the mixture injected to that of healthy pus, was followed by the immediate death of the animal.

Dance considers that the extension of phlebitis in the direction towards the heart, is a proof that pus acts as an irritant on the inner coat of veins; but there are three objections to this view, which appear to me to be fundamental.—1. The fact that the inflammation very often extends in the contrary direction; 2. That, as the researches of Mr. Arnott have shown, it generally stops suddenly at the point of junction of the diseased vein with some large branch; 3. The inflammation generally runs to its full *extent* before any pus is formed at all.

PRACTICAL SUGGESTIONS.

By J. Deane, Esq., Chatteris.

Our medical literature is, for the most part, formed by men of leisure, men, too, of vast experience, acquired however with little labour, amidst a concourse of patients very near their studies and their homes. They know nothing of the toil and of the loss of time inflicted on the country practitioner. Their mornings are spent in short rides about their immediate vicinity, and with rare exceptions the rest of their time is spent in literary ease among the wise, both books and men. These are the men to bring out medical truths in philosophical dress—to clothe them in the attractions of classical language—to illustrate and adorn them with facts collected from the collateral sciences, and to make them savour somewhat of the genius and learning so generally imputed to the sons of Æsculapius.

The rural practitioner is not "equal to these things." We soon take the stamp of circumstances and humble ourselves to the only status which they permit. If we mean to present ourselves in the galaxy of talent which spreads itself through every page of the Medical Times, we ought first to persuade a Herschel to prove that some stars are altogether in the rough; and, if positively hemispheres, that some remain in the primitive granetic form and structure, as yet unclothed with alluvial verdure and beauty. The rural practitioner spends his life, Cossack-like, between his saddle, his meals, and bed; and yet *he* might be induced to contribute much, very much, to the facts of the profession. What a noble legacy to the world might be left by some of our most experienced physicians, were they merely to state towards the close of their long and usefully spent lives, the chief peculiarities of practice, about which they have satisfied themselves, so that the hint might be taken by others, and some useful plan adopted in many a forlorn case where the ordinary resources of art are either useless, or very uncertain; or so dilatory as to be hardly worth the name of treatment. This, after all, is the noblest aim of all medical literature. Instead of having book upon book, as we too often have, of the same proposition in a new form, we should have at least the comfort of novelty; and if we had sometimes to reject a premature generalization, we should often receive a valuable addition to our therapeutic agencies.

As a very humble contribution to this sort of medical composition, I wish to bring before the profession, what appears to be a new remedy in Chronic Gleet; if it is an old remedy, it is certainly at present much neglected.

Every surgeon has been at times tormented with the dilatory progress of such cases. I well remember the observation of an eminent physician on this subject: "that one sort of treatment was as good as another, and that time alone would wear it away." We all remember the statement of Hunter, that, "there is something scrophulous in some gleets," which he assigned as the reason of their occasional incurability. The sort of case alluded to, is the following: the inflammatory stage is cured; some weeks have elapsed, there is little or no stricture, and yet the discharge continues. We are quite sure that some sort of local irritation would suit the case, and we have, perhaps, tried all sorts of injections, in all possible modes—strong and weak—frequently and rarely: we have also tried the well-known remedy of blistering the groin or inside of the thigh. Constitutional remedies also have failed. We all know how often the cure of such cases is ushered in by gonorrhœal rheumatism, chiefly in the knee joints. Gleet will often bring on rheumatism in the knee joints, and blistering the knee will often bring on violent strangury. This latter calamity is too frequently the lot of the poor invalid, whose knee requires to be blistered for disease of that articulation. Now, although we do not know by what process gleet will often bring on gonorrhœal rheumatism, we do see some positive reason for the relief derived by a gleet, from an attack of gonorrhœal rheumatism: it arises partly if not wholly from counter-irritation, acting the more rapidly in this case, from the unexplained sympathy between the urethra and the knee joint. It occurred to me three years ago, (May, 1843) in managing a case of chronic gleet which had resisted for nineteen months, every mode of treatment adopted by other practitioners, as well as by myself, that we might obtain this counter-irritation quite as well by a blister around the knee; that with the certainty of art we might act on this sympathy, and obtain an articular irritatoin as useful as any which the uncertain and dilatory operations of Nature might give, with this differential advantage, that by applying the blister, we should most probably obtain strangury, and that by the combined action of irritation relieving the special chronic excitement in the urethra, and of strangury substituting one irritation in the part for another, we might at once free the urethra from disease. I believe the false membrane formed in severe strangury has been recently *discovered*—that is to say, has been recently written about, perhaps it is in this way only, that I did then discover what had been known before, but not written about: I had often seen this false membrane in the urine passed in strangury, and I relied on it as justifying the hope of change in the urethral surface. In this, my first use of the remedy, strangury came on during the night; films of detached membrane were visible in the urine; the gleet was considerably checked by morning, and entirely disappeared never to return, before twenty-four hours from the application of the blister. Encouraged by the history of this case, I have adopted the same plan in at least twenty cases of chronic gleet, and have had nine cases that have yielded as rapidly to the treatment, and not one that was not very plainly benefited by it. In some cases, I have applied the blister twice, and in one three times. I have not had any trouble with chronic gleet, since the addition of this to our other plans of treatment; and although I do not expect for any length of time to remain so fortunate, yet I am quite certain that whoever adopts it in the sort of case which I describe, will find it a valuable addition to the resources of our art. If it has been elsewhere adopted, it has been a part of the "hidden wisdom of the wise," "not to be found in any of the books;" and but for this opinion, I would not have presumed to bring the subject so prominently before the profession.

As I said before, we want some of our old practitioners to tell us their experience in the treatment of disease. I know I shall expose myself among the fastidious to the charge of being miscellaneous, but I wish, at whatever cost, to let our old practitioners see how easily they might make a "book," and that it is no more necessary to keep to one point in scribbling, than to one point of the compass in an ordinary midnight gallop.

What is the best treatment for a certain class of cases, termed "Acute Rheumatic Fever;" the case for which Bouillaud used, Sangrado-like, to adopt bleeding coup sur coup, within an ace of death, and repeated as often as reaction set in? What the result of this practice is, in France, I care not to know: if practised in Cambridgeshire it would be "hominem jugulare," and had better be done from the carotid or innominata, for brevity's sake. It is now thirteen years since I first witnessed Dr. Hue's plan of treating such cases at St. Bartholomew's, and I never knew anything in physic more satisfactory. I have practiced it ever since, and I regret to find no mention of it in any of the numerous practical treatises which I have since read on this subject.

What a variety of plans have been adopted in these cases, and with hardly any result! What tedious illnesses have they not introduced! I have seen scores of them vanish in three or four days, under Dr. Hue's plan of management, *provided the treatment has been commenced with the first decided symptoms of the disease*; and I have been almost as successful in these cases in the humble imitation of so able a preceptor. Before attending St. Bartholomew's, I had been led to prefer the calomel and opium, preceded by venesection, but was soon obliged to make it yield to "the nobler and the better one." My readers (if I should have any) will soon say "with what simplicity the world is governed," when I inform them that Dr. Hue's plan consists in the use of the inspissated juice of the recent colchicum bulb. He recommends the plant to be kept constantly in the soil ready for use, and the pills to be made when wanted. Unless pericarditis be present, venesection is not to be resorted to. No purgative is to be administered unless the bowels are very much confined; and then castor oil, with warm water enema, will suffice. The object of these precautions is to kee

the system fit to receive the colchicum, which might become ineffective if any active treatment were first tried. For an average state of system five grains every eight hours for twenty-four hours, then every six hours for twenty-four hours, then every four hours for twenty-four hours, and then every three hours, until it acts on the system, is the very brief prescription; and it very rarely requires to be carried beyond the third or fourth day. The patient should be seen at least once a day, and the attendants should be instructed to omit the medicine as soon as its action is developed. In most cases extreme exhaustion with diuresis is the only symptom—in some, catharsis—in some, hypercatharsis, in prospect of which contingency, a small dose of laudanum, in brandy and water, is provisionally named as the best remedy. The pulse is in most cases moderated before the lapse of twenty-four hours, and the fever somewhat abates; but no absolute relief is felt by the patient until some such feeling is experienced, as is well known to be the effect of colchicum administered in the ordinary way; and contemporaneously with these exhausting sensations, every trace of the disease will generally disappear. I have never known the small quantity of colchicum used in this way act disagreeably as the vin. colchici often acts; and I am certain that the colchicum prepared in this manner acts on rheumatic fever in the acute form, far more certainly, as well less disagreeably, than any other remedy. The plan will rarely fail, and when it does, the disease very soon yields to a slight ptyalism. It is only in the commencement of the case, however, that such results can be expected: to its subsequent stages the plan is inapplicable, and then cases so much vary that few general remarks can be made. There will also be cases of acute rheumatic fever, to which Dr. Hue's plan will be inapplicable; as in anemic or consumptive complications—in advanced pregnancy—and in all those cases where a prudent practitioner would avoid the colchicum in any form. But with these qualifications, I do think, from having made this form of disease a special study both by the plan of treatment now named, and by the plans in ordinary use in the profession, that few cases of this type will occur in which it will not arrest the disease in such a way as to merit the best compliment that can be appended to any treatment, tuto, cito et jucunde. It is safe, for although I have been familiar with it for thirteen years, I have never seen any evil result from it; and this is the observation of the very distinguished physician whose name I have so often used in this paper. It is quick, generally converting a two-month's illness into an affair of from three days to a week. It is the least disagreeable of plans, for its only effect is temporary exhaustion. It does not relax the system, the ordinary result of other methods; and by rapidly checking the disease, it soon gives the poor invalid the "jocund" satisfaction of placing his agonies among the things that have been.

It is much to be regretted that while some of our metropolitans ramble over the entire civilised world to note down and describe the follies and the wisdom of our great men, it should be left to a "poor provincial" to name a therapeutic fact involved in the clinique of one of our own hospitals, equal to any which our medical annals "can boast through all their dismal dark duration."

QUACKERY IN WALES.

By Evan Thomas Esq.,

Late House Surgeon to King's College Hospital, Fellow of the Royal Medical and Chirurgical Society, London, &c.

M. O. aet. 31—married—the mother of one child; has always enjoyed excellent health; she recovered quickly from her first confinement; the labour, in every respect, a natural one. Attended by a midwife.

In her second confinement she was attended by "quack doctor," who, when first informed, promptly attended, and pronounced her to be in labour, asserting at the same time that it was incumbent upon him to perform an operation; this manœuvre was no more than rupturing the "membranes," though, ever characteristic of the charlatan trickery, he made it to appear something very formidable, as, indeed it turned out to be in its consequences.

For a time the labour pains increased in force and frequency, but they gradually failed till they almost entirely ceased, without effecting delivery; much in this dilemma the poor woman was allowed to remain for two days, when, the worthy sage declared it to be his duty to deliver, at the same time premising that the child was dead. He proceeded to fulfil his promise, having first availed himself of a country blacksmith's dexterity; he had a hook made similar, at the end, to a pot hook (as the kitchen maids I think call it) but having a much longer leverage power. Thus prepared, he succeeded, after oft and repeated efforts in delivering; the child being dreadfully mutilated about its head and face was, of course, still born.

On the day following this savage procedure, I saw this woman, she was then in a very weak exhausted state, complaining of severe abdominal pain and tenderness; placenta still attached, or rather detained at the neck of the uterus; upon examination I could detect no pelvical injury, other than a rent in the perineum. This woman, ultimately recovered; leeches and fomentations, were at first applied to the abdomen, the vagina was daily washed by means of a syringe; water-dressing to the perineum: the inferences which may be drawn from the preceding case, are,

First, Had this woman been left to nature, that is, if the natural efforts of the mother had not been defeated at the outset, the probability, nay, even the certainty of the mother's safe delivery of a living child will not be doubted.

Secondly, Had this woman been under the care of an intelligent practitioner, he would have foreseen the utility of using (if necessary) some other instruments better fitted to her condition, at once obviating the depression which the constitutional and mental distress so prolonged could not fail in producing. The premature rupture of the membranes had a fair share in rendering the labour tedious, if it were not the sole cause.

Thirdly, The miraculous escape, from the most formidable accident which can befal a female, namely: a recto-vaginal, or vesico-vaginal fistula, one or both.

A. R. aet. 39—married, and the mother of eight children. All the former labours have been natural, in none has she needed instrumental interference; in her ninth confinement she was attended by an ignorant midwife, but she was safely delivered of a living child, before the midwife arrived at her residence; the placenta was not yet expelled, and she commenced to disengage it by gently pulling at the cord, but finding the gentler motions failing, she allowed her intrepidity to get the better of her sagacity, and so exercised it, till at last she tugged away the placenta and the uterus with it inverted, the former still adherent, to the latter, a flood of hemorrhage instantly followed, accompanied with faintings, and in about ten minutes she expired, in a convulsive struggle. The placenta owed its firm attachment to the existence of ossific deposits, between the placental tufts, and the lining membrane of the uterus.

Remarks. Even the most sceptically disposed, will not, I presume, maintain two opinions about the immediate cause of the inversion which followed this barbarous procedure: some have so much false humanity about all their proceedings, that, even in such a distressing instance as the above, they would be disposed to turn a deaf ear to the re sub judice, and be inclined, like justice, to the side of mercy; it will but admit of one explanation, in my opinion, which is, that the force so indiscreetly applied was the cause of the inversion, and this with its concomitants, the cause of death. The poor woman was in bed from the beginning to the end of her labour, therefore, strong uterine action added to this, the upright posture could have had no share in bringing about this sad event; besides the uterus did not remain wholly inactive after the expulsion of the child, there being no hemorrhage calling for immediate extraction.

So much has of late appeared in the very clever editorial articles of the *Medical Times*, in favour of the much abused *General Practitioner*, as well as against *Quackery* in every shape and form, that there cannot exist in the minds of the unbiassed, any doubt of the *Medical Times* being the *General Practitioner's* only adviser at this critical period, in medical politics. It strikes me that our legislators are too chary in abridging the liberty of the subject, even, when it may tend to his own destruction.

It remains for the National Association, composed as it is of so vast a number of the best informed in the profession, to frame restrictive laws that shall, let us trust, prove effectual for the safe suppression of quackery.

What would certain of the "pures" have the public believe to be the acquirements of the General Practitioners, judging from Mr. Lawrence's mealy-mouthed effusions? Do not the general practitioners, at least the majority of them, possess as much, if not more, general knowledge of their profession than the pures do? The one is daily called upon to treat diseases requiring the greatest tact and nicety—the whole range of medicine strictly so called. As an obstetrician, he has to decide on the existence of pregnancy, and this is not always free from difficulties; and, to perform the trying and responsible duties of instrumental delivery; he has to decide, by an appeal to his conscience as well as to his experience, whether he shall destroy the life of one to save that of the other, or risk both the mother and the child, with the view of saving both. Nevertheless, the pures must be considered superior as surgeons? Some are, others are not so. A senior surgeon to a London Hospital, an Examiner at the College, was once asked by a junior surgeon of the institution to diagnose, in a case which perplexed him; I happened to be an eye witness, as well an ear witness, to this. The case was a chronic strumous abscess, over the upper portion of the *sternum*, its nature was evident to a very superficial observer: the gentleman pronounced the case, true enough, to be an abscess, and satisfied himself by plunging a very narrow bladed bistoury into it, the escape of the contents fully verifying what he had said. He indulged himself, afterwards, with the following astounding clinical remarks, "That if it were aneurism a puncture would not be followed by any bad consequence" adding "that a bit of sticking plaster would effectually stop the bleeding:" what will be the next discovery? a bit of sticking plaster stop the bleeding from an aortic aneurism!

HOSPITAL REPORTS.

MEDICAL TIMES PRIZE CASES.

FIRST SERIES.

Reported by J. S. FLETCHER, Esq., Student at the Manchester Royal Infirmary.

SURGICAL CASES.

Case IV.

Severe Wound of Knee-joint—Portion of Cartilage torn from the end of the Femur—Foot of the opposite Leg blown off—Severe Contusions—Recovery without the slightest injury to the functions of the Knee-joint.

Joseph Payne, aged twenty-three, a miner, from Woodhead, was admitted into the hospital on the 18th of January, 1845, under the care of Mr. Turner. The persons who brought him state that he was assisting in blasting some rock, when the explosion took place before he had got more than a few yards away from the spot, and he was struck by several very large portions of the rock, which knocked him down, and he was picked up quite senseless. When admitted into the hospital, it was found that there was a large lacerated wound, several inches long, on the inner side of the left knee-joint; there was a quantity of synovia flowing from it, the whole length of the wound communicating with the joint, and a portion of cartilage, about the size and thickness of a half-crown, was protruding from between the lips of the wound; this was connected by a

small portion of synovial membrane to the end of the femur, from which it had evidently been torn or cut off by a portion of the rock. The parts around were much contused. There was rather free bleeding from the wound. The end of the right foot was blown off, all the toes being gone, and a good part of the soft parts covering the ends of the metatarsal bones, which projected from the wound and were bare. On the left side of the forehead there was a large scalp wound, extending down to the bone, which was not fractured. Besides these more serious wounds, he had several less severe bruises and slight wounds over different parts of the body. He was in a complete state of collapse from the injuries; extremities were cold; surface pale and cold; pulse extremely weak and frequent; countenance sunken, pale, and anxious; but he was quite sensible, and answered questions rationally.

He is a fine, robust, muscular man, and states that he has at all times enjoyed extremely good health. He has led a very regular life, has never drank much, has always had good diet, and been accustomed to very laborious work.

He was put to bed, the loose portion of cartilage was removed from the wound at the knee-joint; its edges were brought together by strips of adhesive plaster, and cold wash applied over these. The foot was enclosed in a large poultice, and the wounds were dressed with adhesive plaster.

19. He has passed a restless night; has not recovered from the collapse; pulse is very weak; surface cool; countenance pale and anxious; has passed some urine; makes no complaint of pain except in the foot and knee; there does not appear to be the slightest action going on in the wounded foot; no swelling or increase of heat in the knee Continue dressing.

20. Had some low muttering delirium in the night; he is not so low as yesterday; pulse is more full; surface warmer; tongue slightly furred; some thirst; bowels not moved; passes urine freely; foot and knee same as yesterday.

21. Had a tolerable night, but slept little in consequence of pain from the foot; pulse 102, full and soft; skin warmer; tongue furred; some thirst; bowels moved; passes urine freely; foot painful; no action going on in the wound; knee easy, and free from swelling.

22. Slept little in the night; leg and foot were very painful; pulse 105, and soft; surface natural; tongue moist and furred; thirst; anorexia; bowels open; passes urine freely; is free from pain, except in the foot, the wound on which is quite inactive, and there is much swelling of the leg above; knee quite easy; scalp wound is doing well.

Vespere. Has still considerable pain in the foot; in other respects remains as in the morning.

℞. Morph. acet., gr. ½; Spt. æth. nit., ʒj; Mist. camph., ℥ij. s. s.

23. Had rather a better night; pulse 130; slight increase of pyrexia; bowels rather freely open; says he is free from pain, except some little on the foot, the wound on which remains languid and inactive; knee the same. Rep. haust. h. s. s.

24. Has had a restless night; had severe diarrhœa, which still continues; tongue is dry and furred; much thirst; anorexia; no tenderness or pain in the bowels; passes urine freely; pulse full, soft, and 132, skin hot and dry; he is occasionally delirious; foot and leg painful; the wound is still quite inactive; there is some increase of the swelling in the leg; knee easy and free from swelling.

℞. Tinct. opii, *m*. xxx. h. s. s.

25. Was restless, and had much delirium through the night; pulse is 125, soft, and full; skin hot, but more moist; tongue more furred; great thirst, diarrhœa has continued severe, and still remains so; he has no pain or tenderness of the abdomen; passes urine freely; foot painful; not the least appearance of suppuration; wound is more moist; swelling of leg continues; knee easy; no swelling or increased heat. Rep. tinct. opii.

26. Had some delirium, and was restless through the night; pulse 120, and smaller; skin hot; had much pain in the bowels, and very severe diarrhœa, being up almost every half-hour; tongue dry and furred; great thirst and anorexia; passes urine freely; foot painful; there is a small spot of granulations, and a little pus upon it for the first time; knee easy, no swelling; the right arm was slightly bruised, and is now considerably swollen and inflamed from erysipelas, extending from below the shoulder to the middle of the forearm. To have cold lotion to the arm, and rep. haust. morph. h. s. s.

27. Has continued delirious and restless; pulse 126, and small; diarrhœa continues very severe, and he has much griping pain in the abdomen; other symptoms same as yesterday; erysipelas of the arm has not extended; scalp wound healing.

℞. Mist. cretæ, ℥vj; Tinct. opii, ʒj; M. ℥j omni secundâ horâ sumend.

28. Has slept well, and had much less delirium; the pain in the bowels and diarrhœa have subsided; pulse is 115, hard, and more full; tongue moist, but more furred; great thirst; anorexia; erysipelas of the arm has subsided; foot is easier; it is now almost covered with granulations of a healthy character, and there is considerable quantity of healthy pus; knee quite easy.

29. Has had a good night; no delirium; diarrhœa quite checked; less pyrexia; pulse 114; is free from pain, except a little in the foot and knee, but there is no swelling or increase of heat in the latter. Omit. mist. cretæ and poultice to foot, which was ordered to be dressed with warm water dressing.

℞. Tinct. opii, *m* xx. h. s. s.

Feb. 1. Has continued to improve; pulse 84; is much more free from pyrexia; bowels are quite regular; passes urine freely, which deposits a large quantity of lithate of ammonia; knee is easy. The plasters were removed to-day for the first time; wound is filled up with healthy granulations covered with healthy pus, and there is not any surrounding swelling; foot more painful; wound healthy.

4. He appears much better, but says he has not had much rest for two days; pulse is 82, full, and soft; skin cool; tongue moist, but little furred; less thirst; appetite improving; bowels costive; passes urine freely; foot easy; wound healthy; ends of metatarsal bones separating; knee easy; wound filled up with granulations.

℞. Haust. sennæ co., ℥ ij. s. s.

8. Sleeps well; is free from pain, and has continued to improve; pulse 80, soft, and regular; appetite improves; is free from pyrexia; bowels costive; foot and knee are both doing well; wounds healing at the edges; scalp wound is almost healed.

11. Continues to improve slowly; is free from pain or pyrexia; knee and foot easy; wounds healthy and healing.

13. Had considerable perspiration throughout last night; no shivering; pulse 80, full and soft; tongue clean; no thirst; appetite not so good; bowels costive; passes urine freely; foot more painful, but wound continues healthy; knee easy; wound half healed; granulations on other part pale and languid.

℞. Haust. sennæ co, ℥ij. s. s.

15. Has had a very restless night; was suffering from very severe pain in the right side, with which he was seized last evening, and which obliged him to sit up the greater part of the night; it still continues very severe, is increased by each inspiration, but not by pressure; he has slight cough without any expectoration. In the infra-lateral and lower part of the scapular regions on the right side there is some dulness on percussion; the respiratory murmur is indistinct, and there is a slight friction sound a little higher up; sounds normal over every part of the chest; pulse 103, full; skin hot, but moist; he had profuse partial diaphoresis during the night, succeeded by an attack of shivering, which held him for three or four minutes; this occurred three or four times during the night; tongue furred and dry; thirst; anorexia; constipation; passes urine freely, which deposits a copious precipitate of lithate of ammonia; foot and knee easy; wounds languid.

℞. Haust. sennæ co., ℥ ij. s. s. To have sinapism to side.

16. Has continued to suffer from the severe pleuritic pain in the right side; it was much worse in the night; was increased by paroxysms and by inspiration; pulse quick and hard; surface hot; some thirst; bowels freely open; knee and foot the same. Sinapism gave him some relief, and he was subsequently ordered to have hot fomentations constantly applied to side.

17. The pain in the side is much easier; the hot fomentations, he says, relieved it; he can now breathe with much more ease, and dry cough is gone; pulse 100, soft, and smaller; skin cooler; tongue cleaner; appetite better; foot is more painful; wound is suppurating freely; knee easy; wound healing.

20. Has continued better; passed a good night; almost entirely free from pain in the side, but has a slight cough; pulse 85, full, and soft; skin natural; breathes easily; dulness on percussion over right side quite gone; tongue clean; appetite improves; bowels costive; knee is more painful; there is some little swelling and inflammation around the wound, extending a little down the leg; foot easy; wound healthy. To have warm water dressings to the knee, over the strapping. Rep. haust. sennæ co.

23. Is improving; is free from pain or pyrexia; appetite good, and bowels regular; knee easier; swelling and inflammation around wound subsided the day but one following, and are now quite gone; foot is doing well. To have a generous diet.

26. Has passed two good nights; is free from pain or uneasiness, except a little in the foot; has no fever; appetite very good; bowels are regular; foot more painful; the granulations on the wound are high, its edges are red, and it does not appear to be healing; the ends of the metatarsal bones have separated; knee easy, wound healing. To have foot dressed with strapping plaster.

29. Continues in the same state, except that he has a little more pain in the foot.

March 2. Is improving in strength; has good nights; is free from pain; pulse 80; bowels regular; appetite very good; knee easy, wound almost healed; he has considerable power over the joint, can bend it considerably, and can support some weight on that leg; wound on foot is more healthy, and is healing.

4. Is complaining of some headache; pulse 75, soft, and regular; skin natural; tongue clean; no thirst; bowels regular; appetite very good; knee is very painful, it began yesterday; there is a small abscess forming on the inner side of the ligamentum patellæ, over the head of the tibia; the wound appears healthy; wound on foot cicatrising at the edges.

6. Headache has ceased, and he appears pretty well in health; the knee is easier; the abscess was opened yesterday, and discharged a quantity of healthy pus; the original wound is healing. To have one pint of porter daily,

11. Continues to improve in health, and gains strength. Knee has been quite easy; wounds are as near healed as possible; foot easy; wound gets somewhat less.

16. General health is daily improving. Knee easy; wounds are perfectly healed; the joint has its natural shape, and he has some degree of motion in it; wound of foot heals very slowly.

25. Continues pretty well in health. Knee easy; foot is easy; wound healing.

April 3. Continues to progress favourably; he now gets up, and moves about the ward; says he feels much stronger. The knee continues easy; he has a considerable amount of motion in the joint, which he exercises by using passive motion daily; wound of foot is less.

15. Says he feels quite well of himself. The foot has been rather painful; wound has been very languid, and is almost stationary—a small portion of bone came away yesterday; knee easy; he gradually gains power over the joint, and can now bear without pain the whole weight of his body on that leg.

22. Says he improves in health and strength. Foot has been uneasy; wound has been looking irritable and unhealthy, there has been a considerable discharge of the serous matter from it; knee improves daily. Omit strapping to foot, and to be dressed with ung. zinci.

27. Foot is easy; wound is looking much better; it is cicatrising at the edges, and granulations are healthy; knee improves; health continues good.

May 5. Has continued in tolerable health. Foot healing slowly; he daily gains more strength and power over the knee-joint.

17. He has continued in the same state, the foot healing slowly, and knee improving, until within the last day or two, since which time his appetite has been falling off a little; in other respects he

remains the same in health, but the wound on the foot is looking languid, and is not healing at all.

21. Is up and moving about the ward as usual, but appetite is not good; tongue is clean; bowels regular; pulse full and soft; passes urine freely, and is free from pain, except a little in the foot, the wound on which looks worse; granulations are pale and flabby, pus is thin and sanious, the edges are of an unhealthy red aspect and are ulcerating.

22. He had an attack of rigors this morning, which was followed by some griping pain in the abdomen; vomiting and diarrhœa; tongue is furred and dry; he has thirst, anorexia, and frequent inclination to vomit, with alternate attacks of hot and cold; pulse is quick, full, and soft; skin hot; passes urine freely; foot is easier, wound the same.

R. Mist. amm. acet., Mist. antimonialis, āā ℥vj; M. ℥j omni tertia horâ sumendâ.

24. Is considerably better; is free from pain in the abdomen; tongue is cleaner and moist; no thirst; anorexia continues; bowels more regular; pulse less quick; foot easy; wound less languid, and seems larger; knee continues to improve; he daily gains more power of motion over it, and can now walk upon it very well. Cont. mist.

27. Is free from pyrexia; tongue is clean; appetite is improving; bowels are regular; passes urine freely; foot painful; wound languid, and much increased in size by ulceration of edges; it discharges a thin sanious matter. Omit ung. zinci. Apply lotio cupri sulph., and to have it strapped again.

June 3.—Says he feels better of himself; tongue is clean; bowels regular; appetite improving; pulse natural; wound on foot is now looking more healthy; he has now gained the normal use of the injured knee; he can move it freely in every direction without suffering the least pain or inconvenience, and can support his weight and walk upon it with ease; in fact, he says it is quite as good, if not better, than the other, which is somewhat stiff from lying so long in one position. He was made an out-patient, and left the hospital.

REMARKS.

The aspect of this case at the time of his admission was most unpromising, and little or no hopes could be entertained of his ultimate recovery; but the result of the case shows how far a good constitution will bear a man up against severe injuries. The severe shock which he received from the injuries, aggravated, no doubt, very much by the opening and wound of so large a joint as that of the knee, caused such a state of collapse that it was even doubted whether he would overcome it. It is remarkable the effect which the opening of a large joint has at times upon a person previously in good health; it will sometimes bring on instantaneous severe collapse, hence one of the dangers of operations upon them. Supposing him to overcome the collapse, it was probable that with reaction there would be severe inflammation of the joint set in, and he would again have to contend against one of the most dangerous consequences of injuries to joints; fortunately for him, however, this did not occur. Inflammation of the joint was probably prevented first by the mode of dressing adopted, by which the wound was closed as perfectly and as soon as possible, avoiding the use of sutures. These are circumstances to be observed in the treatment of all wounds of joints, and, when adopted soon after the injury, contribute much to the ultimate recovery. The severe injury of the opposite foot and other injuries, with the supervention of severe diarrhœa immediately on the first occurrence of reaction, were all circumstances which may be said to have acted as concomitants, and to have directed Nature's efforts to other channels than to the setting up inflammation in the joint. To have checked the diarrhœa at first would have been to allow of the setting in of severe reaction, and with that probably of severe synovitis; it was much better to allow this to continue, so long as it was compatible with safety, and then to check it, and not before. The effect which this had in keeping in check the action in the wounds, was visibly shown in that of the foot, as will have been seen from the report of the case on the 28th of January, and a few previous days. It thus assisted to accomplish what the surgeon would have sought to do by the use of the lancet and other means. A moderate degree of inflammation was necessary for the repair of the injury to the joint; it was an excess of this that was to be feared, and it is its moderation within due limits which is the grand object of treatment. If the inflammation be very severe, it may terminate in one of two ways—either it may cause such injury to the joint and constitutional disturbance as to terminate fatally; or more frequently it will cause such injury to the textures of the joint as to result in anchylosis; this latter was the most fortunate termination expected in this case, considering the injury already done to the cartilage and other parts; but from the reports of the case it will have been seen that there was little or no inflammation resulting, that the wound healed kindly and rapidly with very trifling discharge, that he suffered no pain from it of any moment, and that he ultimately recovered the full and free use of the joint, much to the surprise of all who saw the case. The small abscess which appeared about the knee in the latter part of the case, was confined to the integuments, and was prevented extending further by being timely opened.

The slight attack of pleuritis which occurred, proved of trifling import, as it was rapidly recovered from. The wound on the foot was healing slowly and kindly for some time, but ceased to do so after he had been in the hospital some months; at the same time he began to suffer from anorexia and slight pyrexial attacks, most probably resulting from long confinement, and the air of the hospital, so that a change of air would be productive of benefit.

This case points out to us the fact, that in some severe wounds of joints, where amputation of the limb would formerly have been adopted, we may, by immediately and accurately closing the wound, and this if possible without sutures, keeping the limb perfectly motionless, and directing our efforts to the checking of inflammation, if it appear, occasionally succeed in saving the joint; and it offers an encouragement for the trial of this where even latterly it would not have been adopted.

MANCHESTER EYE HOSPITAL.

By A. W. Close, Esq., Grosvenor-street, Manchester.

Since I wrote my last communication, (page 10) I have observed that Mr. Lawrence in his "Treatise on Diseases of the Eye," comments thus, on Milton: "Even our great poet, who might have been supposed to find every alleviation and resource that such an affliction admits of, in his highly gifted mind, and the exhaustless stores of knowledge with which it was furnished, repeatedly reverts to his blindness, and always in a tone of *anguish* and *despondency* characteristic of recent misfortune." How he could draw such a conclusion in the face of the heroic declaration of Milton, "I will, since it is God's pleasure, rather *rejoice* than repine at being blind," I am at a loss to conceive.

As I am about to discuss in these reports, a mode of treatment of purulent ophthalmia, concerning which, there is a diversity of opinion amongst ophthalmic surgeons. I may *in limine* remark, that I am no partizan. I have brought to the investigation, an inquiring, but an unprejudiced mind. Of Mr. Walker, I know but little, save in his capacity of a provincial ophthalmic hospital surgeon, and from his published works. In general practice he is my competitor and rival. Of the metropolitan surgeons, whose names I may have occasion to mention, I know as much, and I must confess that I have entertained strong feelings of respect for their professional abilities, in connection with my alma mater, the Royal College of Surgeons of London. I may not say, as it has been poetically sang of a good man, my "failings lean to virtue's side," but I may say as the editor of this Journal, and many of my professional brethren of this town can testify—my affections have leaned to the side of the college and its ministers. I am not then, it may reasonably be supposed, inclined unfairly or maliciously to criticise any points of practice which they may individually advocate. No cause have I to serve but that of truth—no result to desire but the real practical advancement of the profession—in the promotion of which, names and persons are not of so much moment as their published thoughts and practice. Having professed my attachment to the college, I must add, in justice to myself, that when it ceases to be a *college of gentlemen*, every tie will be severed which binds me to it. I can hardly believe that an individual holding the responsible offices of councillor, examiner, metropolitan and hospital surgeon, can have acted as Mr. Lawrence is reported to have done. No doubt he will take an early opportunity of setting himself right on this matter with the profession and the public. If not—if the allegations remain unanswered and unnoticed, silence may be construed as the admission of their truth, and if so, Mr. L. had better retire at once to some hamlet on the borders of a fen, where he may learn to distinguish "geese" from men.

I will now proceed to the more proper matter of this report. What is the best mode of treating gonorrhœal and purulent ophthalmia? First, I will cite Mr. Walker's views, afterwards, I shall give numerous cases, not selected, but as they have consecutively occurred since I became an eye-witness of the treatment of these diseases at the Manchester Eye Hospital. Mr. Lawrence, in his work on the Venereal Diseases of the Eye, thus expresses his views on the treatment of gonorrhœal ophthalmia: "The only chance of arresting this violent disorder, and preserving the eye from its destructive effects, is afforded by the boldest antiphlogistic treatment; particularly by the freest abstraction of blood, generally and locally. We must bleed largely from the arm, and take blood by cupping on the temples, or by numerous leeches applied round the part; and these measures must be repeated at short intervals, until the vascular congestion is relieved, and the attendant pain removed. The other parts of the antiphlogistic treatment must be combined with this free abstraction of blood; but our great reliance must be placed on the latter." On these views Mr. Walker remarks, "The reader may be curious to know what were the results of that treatment in the hands of so able and zealous a practitioner. I will furnish him with a brief summary. Of the fourteen cases, nine had the disease in only one eye: six of these were lost, and but three recovered. The *other five* were affected in both eyes: of these, one *lost both* eyes; two *lost one* eye; one *recovered both* eyes, with *imperfect vision;* and *one* only recovered completely. So that of the whole fourteen cases, but four can be said to have properly recovered." This is certainly very valuable evidence as to the effects of antiphlogistic treatment in gonorrhœal ophthalmia. This gentleman (Mr. Lawrence) however, "infers not that antiphlogistic treatment is incapable of arresting the inflammation, but that it has not been employed to a sufficient extent; and if I had to treat (he continues) some of these cases again, I certainly should bleed more freely. I think that as much blood should be taken from the arm as will flow from the vein, and that the evacuation should be repeated as soon as the state of the circulation will allow us to get more." And by way of encouragement, he then proceeds to favour his readers with the following quotation from Mr. Bacot on this subject, who heroically observes:—"These are cases which defy all the usual etiquette of regular and ceremonious visits. If we wish to save our patient from the destruction of his vision, we must scarcely depart from his bedside until the inflammatory symptoms are controlled. The lancet must be hardly ever out of our reach, for if ever there was a disease in which blood may be taken away without limitation, it is this." But this is not all: Mr. Lawrence calls in further testimony in corroboration of his views. "Mr. Wardrop informed me (he adds) that the only case of gonorrhœal opthalmia he had seen, in which the eye was saved, was that of a young woman, in whom venesection was repeated as often as blood could be got from the arm. She lost 170 ounces in a few days, and looked as if every drop

of blood had been drained from her body; the skin having nearly the hue of a wax candle." 'As the best commentary I can perhaps offer (says Mr. Walker) on the extraordinary statements here made, as well as to prove the correctness of my view as to what constitutes the proper treatment of this disease, I will now give the history of a case which has recently been under my care; in which the eye was saved by an equally simple and rather less dangerous practice." Mr. Walker then gives the following case.

"Case.—Mr. A. at 19, apparently in the enjoyment of full health, called upon me on the 1st of November, to consult me relative to an affection of his left eye, which had commenced on the preceding day, and which exhibited the following symptoms:—the palpebræ, particularly the superior, were much swollen, and very red. On endeavoring to separate them, there was so much tension as to render it difficult to obtain a view of the eyeball: only the inferior portion of the cornea could be seen, and on it was observed a slight appearance of ulceration, as if in the incipient stage, and quite superficial. The conjunctiva of the inferior portion of the eyeball, was in a state of the most violent inflammation, attended with excessive chemosis, and bulged forwards between the separated margins of the lids. There was a considerable discharge of a thick muco-purulent fluid, which occasioned the tarsal margins frequently to adhere, and there was also a good deal of lacrymation. He had not much pain about the eye, nor was there any constitutional disturbance. The right eye was unaffected. Seeing that it was a decided case of purulent ophthalmia, and confined to one eye, I inquired if he had any gonorrhœal discharge? This he at first denied, but afterwards admitted; and on being further questioned, said that he was not aware of having brought any of the gonorrhœal fluid into contact with the eye, although he appeared to be impressed with the idea, that there was some connection between the two diseases. I immediately applied the *nitrate of silver* to as much of the conjunctival surface, as could be got at, allowing it to remain a short time in contact with it, particularly with the chemosed portion at the inferior part of the eyeball. This produced very severe pain, which continued for about half an hour, at the end of which time he returned home. I advised him to remain at home, indeed, to keep to bed for two or three days, and to have the lids very frequently fomented with warm water. I also prescribed four grains of calomel, h. s. and a draught of the inf. sennæ, cum magn. sulph., seq. mane. The next day I visited him at his own residence, and found the eye much the same as on the previous day. The *nitrate of silver* was again applied, and the other remedies ordered to be continued. On the *third day*, the swelling and tension of the palpebræ were so much diminished, as to admit of their being fully separated, and the whole of the cornea to be exposed to view. The ulceration was found not to have extended; the bulging portion of the conjunctiva had subsided; and the vascularity was much diminished. The discharge was still considerable, and of the same character: the bowels had been kept open by the medicines before prescribed. The warm water was found to be grateful. The *argent. nitri.* was again freely applied to the conjunctival surface of both lids. On the *fourth day*, the eye appeared still better. The *nitrate* was again applied. On the *fifth day*, he was so much improved, that he came to see me. The palpebræ were now nearly of the natural size, the chemosis gone, but the conjunctiva was still very vascular, and the ulceration of the cornea not quite healed. The discharge was diminishing, though still free; he complained of no pain, and his vision was not materially impaired. The nitrate was again applied. From this time the nitrate was applied every other day until the *ninth*, when the eye appeared so much better, that, at his urgent request I gave him leave to go into the country for two or three days, on some particular business. On his return, on the *thirteenth day*, I found all the symptoms aggravated: the swelling and redness of the palpebræ, the chemosis and the discharge had all returned; but not quite to so great an extent as at first. Several opaque spots were observable on the surface of the cornea, which looked exceedingly dim, more particularly at the lower portion. Vision was now more obscured, than at any previous period of the existence of the disease, as he could scarcely discern any object with this eye. The *arg. nitr.* was reapplied, the aperient medicine to be repeated daily, and the eyelids to be frequently bathed with the warm water. The *arg. nitr.* was now applied daily, until the *seventeenth*, when the condition of the eye had again become much improved: the chemosis was entirely gone, but the conjunctiva was still very vascular, the vessels encroaching slightly upon the circumference of the cornea, and forming a red zone around it; the opacity of the cornea was all but gone, but little discharge escaped, and vision was very distinct. The *arg. nitr.* was applied rather lightly, and to the inferior eyelid only. On the *twenty-fourth*, the disease had all but disappeared, slight vascularity, and a little roughness of the conjunctiva of the inferior eyelid, alone remaining, the sulphate of copper was applied. This patient called upon me again, in about a fortnight from the last named date, when the eye was quite well."

"I have given rather fully (Mr. Walker proceeds) the details of the above case, because I consider it a very important and instructive one. It will be seen that the treatment was commenced on the second day of the attack; all the symptoms were of an aggravated character; ulceration of the cornea was already apparent; the chemosis was developed to the fullest extent, and the tension of the palpebræ was excessive; this last symptom, Mr. Lawrence considers to denote the worst kind of case. This case, then, certainly not mild or trifling, was cured without the abstraction of a single drop of blood, and with no other local applications, than the nitrate of silver to the conjunctival, and warm water to the cutaneous surface of the lids."

REVIEWS.

On Tubercle of the Brain in Children. By JAMES MAXWELL ADAMS, L.R.C.S.Ed. [Submitted to the Faculty of Physicians and Surgeons of Glasgow, when candidate for admission into that body, in conformity with the regulations for the admission of members.] 8vo. Glasgow, 1846. pp. 32.

The subject of which this little pamphlet treats is one of the most interesting and important departments of pathology, though, strangely enough, it has hitherto received but a limited share of attention. Monro and Abercrombie were amongst the first to give it a consideration in this country, but not by any means in a systematic or well-digested form. More lately it has been investigated with much care and skill by Dr. Hennis Green, who has contributed very largely to its elucidation. On the continent it is more familiar to pathologists, and it is to our indefatigable brethren in that quarter that we are mainly indebted for what we know concerning it.

The monograph before us does not come with the intention of advancing any new facts of consequence upon the subject, but rather to put together the scattered records of other writers, and so bring them within an available compass, and make them tolerably easy of reference. And its author deserves that it should be said of him that he has executed his task well. We are free to say that his production does great credit to his literary research, as well as to his scientific knowledge and bed-side judgment.

The symptoms of acute tuberculisation of the brain are thus described by Mr. Adams:

"During a state of ordinary health, and after some evident exciting cause, as a blow or fall, or more frequently when convalescing from some infantile disorder, a child is suddenly seized with convulsions, headache, or vomiting, followed often by paralysis of the lower limbs, or one side of the body; The pulse becomes quick, and the child is feverish; various lesions of the organs *(functions?)* of sense supervene, as strabismus, loss of sight, of hearing, or diminished sensibility of the cutaneous surface of the side of the body; the bowels are commonly constipated, and the appetite fails; the intelligence meanwhile remains good. The child continues in this condition for a period varying from a few hours to a fortnight, and seldom longer than three weeks, and death finally ensues, attended with coma or convulsions."—pp. 13 and 14.

The expression of the face in these cases appears to be a valuable diagnostic sign. Mr. Adams dwells particularly upon it, and quotes from Gerhard, who says, "it is so peculiar, that the sister of the wards at the Children's Hospital was accustomed to distinguish the disease with much accuracy from the mere aspect of the child. The face is pale, with occasional flushes of redness on one or both cheeks; mouth frequently a little deviated; lips compressed or half open; the eyelids are almost invariably closed or a little separated; nostrils widely dilated. But the most distinctive character is the peculiar listless expression, with occasional grimaces and movements of the lips, as if tasting an article of food; this character does not admit of description, it must be seen to be appreciated." (p. 25–26.)

Unhappily, the diagnosis of the disease, and a knowledge of its correct pathology, aid us not at all in its treatment. It is one of those ailments that seem fated to be beyond the influence of all our remedies.

TO CORRESPONDENTS.

We have to thank Dr. Davis *for his valuable communication.*

Mr. Arlidge.—*The mistake, indeed, is a ludicrous one, but not one, we should imagine, likely to be of much importance.*

S. M.—*We have had no practical experience of either of the systems referred to, and we decline giving our correspondent any advice on the subject. Cramming for examinations is generally only the resort of those who have neglected the opportunities afforded them for obtaining sound and available information. To stammer through an examination merely, is not, or ought not to be, the aim of a medical education. S. M. should bear in mind that he may, as a medical practitioner, have the life and health of thousands dependent on his skill and information, and serious will be his responsibilities should he, by omitting to gain useful knowledge, waste time never to be recalled, and neglect to fit himself for his duties.*

The Physiological Pons Asinorum *is incomprehensible.*

Amicus Humanitatis *is anxious for the formation of the general medical annuity fund, to which he would himself become a subscriber as far as his means allow, and which he feels confident would be supported by numerous members of our profession. Our correspondent suggests that the rich members of the Council of the College of Surgeons should set an example to their poorer brethren by subscribing handsomely.*

A Constant Reader *in the* Pharmaceutical Number *of the* Medical Times, *will find his request complied with in the present number.*

H. B.—*A minor cannot enforce his claim for surgical attendance. How could a minor have become legitimately a member of the profession?*

M. D.'s *unfavourable opinion of Dublin as a medical school is not reciprocal.*

Numerous correspondents who have addressed us in terms more or less deprecative of the mode in which Mr. Liston secured the succession to Mr. White, as college examiner, are thanked for their communications. We have anticipated their general wish.

Mr. Madden.—*There is no such relationship. The folding depends partly on the booksellers and newsmen. Care, however, shall be taken at the office to leave nothing to their accuracy. The paper will be sent.*

Mr. Danford.—*The parish giving the order for medical relief can enforce payment on the parish to which the pauper belongs. The medical officer should be paid by his own parish.*

Mr. Wilde *shall have a private note.*

N. F. V.—*Six years' standing in a foreign university is requisite for the foreigner seeking a Paris M.D.-ship. He must also undergo five examinations and defend a thesis.*

.. ... must avoid such empirics as he would the worst forms of danger.

A number of correspondents have addressed us on various subjects which are each, in their turn, to meet with due consideration.

Numerous books for review have also been received—the most important being Mr. Phillips' *new work on Scrofula. They will all have due consideration.*

THE MEDICAL TIMES.

SATURDAY, APRIL 11, 1846.

Multa ferunt anni venientes commoda secum
Multa recedentes adimunt.—HORACE.

WE may advance as an established fact that the Medical Profession was never in a more unsatisfactory state than at the present moment. It presents a picture of disorganisation complete as could have been limned by a Dante or a Milton. It is a confusion daily worse confounded, each hour showing in its lowest depth a lower still. Physicians—Surgeons—General Practitioners—Apothecaries—Druggists—empirics—form one moving incongruous social mass—mixed, blended, and interlaced—like animalcula under a microscope—in so curious and complex a fashion, that the power of distinction and definition fails us, and we give up the task of classification in disgust or despair. Each seems a part of the other . every one performs the office of all; words and titles are given or taken that have no affinity with functions—the public is bewildered with discrepancies nobody can set right; and thus a liberal and worthy profession made a home to charlatans and a hiding place to knaves, becomes a suspicion to society and a disgrace and discomfort to itself.

Entire as is the anarchy that marks the body practising medicine, it is not more so than the conflicting imbecility existing among the Institutions appointed to protect the science itself. If we turn to the College of Physicians we discover at once that it has failed to reach its destination, and, with wonderful capabilities, has yet contrived *not* to be the College of English Physic. The Fellows, discontented with things as they are, are not less so with any proposal to make them as they should be. They are at feud with the Licentiates—and these are in mutual feud with themselves as extra- and intra-urban practitioners, and in fixed antagonism to the rulers of what is their college only in name. In the College of Surgeons all is feebleness, indecision, and folly. With something wise always being deliberated on, we have something foolish always being executed. The Members are in the utmost disgust—the Councillors in the utmost indecision and anxiety—injury on one side is as severe as ineptitude is enormous on the other—everything is in the worst possible plight—yet there is no hope of a remedy. The Society of Apothecaries, again, to whom a great portion of the active part of the Profession is attached, are, by their own distinct avowal, in a position not less unsatisfactory or unfortunate. They have, it is true, raised professional acquirements, and *endeavoured* to prosecute empirics; but their declaration is decisive that although the only depository of the legal power, they cannot abate, much less suppress, quackery; and that, although raising the qualifications, they cannot equivalently support the social station of their licentiates. In Ireland and Scotland matters are not more cheering or satisfactory. In all three divisions of the empire agencies are at work to increase the evil, to make still more intolerable the disorganisation—yet how stand we for a remedy?

Government has abandoned the task. The work of cure has been avowed to be above the power of her Majesty's ministers. The hopes from that quarter—once so rife—are blasted. The evil is not only admitted, but it is declared too great for the Government to grapple with.

Are we, then, hopeless? Just the contrary. The very extent of the evil—the very absence of the remedy we had hoped for—gives us the consolatory assurance that a change is as near as it is inevitable.

We are at the beginning of wisdom—just learning to see whence deliverance really is to come—just commencing to entertain the only conviction that is likely to achieve something substantial. We are discovering that whatever is to be done, is to be done, not from without, but from within; that the blow for improvement is one that cannot be delegated, but must be struck by "ourselves." The objection is urged that the work is vast and requires an efficient agency. For that reason, we reply, should we leave to no others its performance. We are above all others interested—we are above all others cognisant of the circumstances—we are not deficient in numbers—individually, we do not want either influence or intelligence; we have, then, all the elements about us to accomplish every amelioration that is desirable, if we will only give them fitting employ. If medical men concentrate and use aggregately the powers diffused among them individually, we know of no righteous object sought for by them which cannot be obtained. In the abandonment of legislation for us by Government, there is still, in this topic, matter of congratulation:—what ministers have declined to do we can have done if we please, and, what is more, have it done by the parties from whose agency we should deduce most of our pride—ourselves. If we fail, then, can we say we deserve to succeed, or merit what we seek?

We are not discouraged by the retrospect of how little, during the last twenty years, we have yet effected. The truth is, we have not *tried* to effect much. Till of late there has been no professional movement. We have had, for the most part, but a *Charlatanism* of effort. We have had great noise, much bluster, magnificent promises, turgid *denunciations*, and the Profession has smiled, or sighed, or gaped at the prominent trickeries of one medico-political mountebank after another, as he propounded his remedies from one associated stage after another. But, as a whole, we have taken no part in the performance. Till of late, we have been but the disdainful spectators or well-meaning dupes of the Charlatans, accomplishing nothing, save to aid them to move into squares, or keep clear of less agreeable localities, by their abounding sympathies with professional miseries. Like Holloway's ointment to an ulcerated leg, the gain in cure or cash has been on the wrong side—never on that of the much-bewailed sufferer. Every word of kindness, every speech of sympathy, was so much hard money lost without consideration, and the only men that thrived on floods of benevolent grief were, oddly enough, the "professors" of political medicine that so liberally gave vent to them. They became rich "*a force de soulager les pauvres*," and, alas! the poor were nothing the better for it. We freely grant that the "London College of Medicine," and the "British Medical Association," and the "Medical Protection Assembly," and the Society which, formed at the Hanover-square Hotel, held its meetings at the Princess' Theatre, and the "Committee of Associated Surgeons"—which, like figures from a camera obscura, have come across us in rapid succession like shadows, and like shadows departed—have accomplished nothing for the Profession, notwithstanding all the hopes they were adroitly made to excite, and all the money they were just as ingeniously made to consume. But it would be to libel both the capabilities and the principles of our body to suppose that these bubble companies for medico-political agitation either represented our feelings, or possessed our support. The great mass of medical men were not in them, and the majority of those that were, were not of them. The very cause of their failure is the very ground of our hope for the future. As they failed for want of professional support, we must succeed now that we are beginning to command and organise that support.

Now, how stands our actual position? We affirm there never was a moment when we could better afford to be taught that our hopes of re-organising and elevating the medical community must depend on our own exertions. The repellant and mischief-making associations—"airy nothings"—to which unprincipledness had lent all the little "*actuality*" they possessed viz.:—"a local habitation and a name"—have burst like bubbles, leaving scarcely "wreck behind." A vast obstacle to large combination is thus removed. The adverse side to professional exertion could not—so to speak—be more favourable. How fare we otherwise? Two vast associations—respectable both from the character of their leaders and the number of their members—stand organised at the hands of the Profession, ready to be set in motion whenever the members please—to take the direction which the bulk of our brethren may prefer, and having, if once brought into combined action, the power of achieving actually all the improvements sought for. We have only to will a complete remodelling of professional government to secure it. Whatever we may desire as to classification—whatever seek as to future qualifications—whatever aim at for administrative government—all is within our reach if we wish.

Possunt quia posse videntur.

The conviction of our ability, united to an inclination for its use, is all that is needful. In the existence of the Provincial Medical and Surgical Association, and, above all, in the National Association—the one with nearly two, the other with nearly five, thousand members—we have all the machinery for giving practical effect to our principles. It is for us to say whether we will set it in motion. The present position of medical affairs—as we have endeavoured to indicate—is peculiarly favourable for a decisive movement. The Council of the Provincial Society should no longer hold back. They have a weighty responsibility, and its full discharge, if we mistake not, calls on them to be up and doing. The forth-coming great meeting of an Association they have every reason to sympathise with, offers a good opportunity for a friendly intercommunion. The day is come when the question must be decided—whether, leaving the present corporations as they stand, an institution shall not be established, more national in its character and more scientific in its tendencies, in which every legitimate practitioner—no matter which of the two divisions of medicine he practices—shall be included. The great meeting of the National Association, to be held on the evening of the 17th instant (Friday next), at the Hanover-square Rooms, will do much to express the general opinion on this subject; and we should be rejoiced to find

a concurrent movement under the direction of those who are answerable for the efficiency of the older society in the provinces.

———

——"Quid nobis certius ipsis
Sensibus esse potest? —qui vera ac falsa notemus?

A SINGULAR insurance case was tried at Warwick last week the chief details of which we have no doubt will prove interesting to our readers, inasmuch as they bear an important relation to the responsibilities of insurance companies, and to the duties of their examining officers.

An action was brought by the assignees of a person named Scott, for the recovery of two thousand pounds, a sum for which he had insured his life in the Imperial Office, London. The action was defended on the ground, that, at the time of effecting his insurance, the deceased was not in a good state of health.

Scott, it seems, was admitted into the "Norwich" after an examination by Dr. Ingleby of Birmingham, in May, 1840. Dr Ingleby, who was considered a severe examiner, pronounced the man to be a sound assurer on life. He, however, was persuaded by some friends to enter another office, and after having paid the "Norwich" five pounds as an indemnification for his release, was admitted in May into the "Imperial," after a rigorous examination by Mr Wickenden, a surgeon of considerable eminence at Birmingham. In the December of 1843, the man died consumptive, his age being 31 years.

The plea set up by the company for refusing payment, was, that the man had spat blood prior and subsequently to his insurance, and therefore, that at the time of effecting it, his lungs were affected with the disease that finally killed him. They called several witnesses in support of this, and strangely enough, most of them were relatives of the deceased. One uncle swore that he never considered his nephew healthy, that he was constantly ailing, that he had generally a cold, and cough with expectoration, and that he frequently expressed a fear of dying consumptive as his father had done. Another uncle deposed to pretty nearly the same things, and added that, when Scott slept at his brother's house, they heard him coughing nearly all night long. The wives of these witnesses made similar statements. The sister of his widow corroborated all that had been said before her, and the widow herself backed them all up, and added further that her husband had never been well during the time he lived at Birmingham. A Mr. Colliss testified to the man's frequent indisposition, to his spitting blood, and his repeated expression of a wish that somebody would make a new pair of lungs for him. Mr. Greatrex, surgeon, said that he had attended him for acute pleurisy, with cough and hæmoptysis; and Mr. Cheetham, a surgeon, said that he attended him in 1836 for cough and spitting of blood, and again, in 1838, for cough and expectoration of mucus streaked with blood.

These evidences were certainly very strong, and might have tended considerably to annul the policy, but that their authorities were not all of them unexceptionable. The widow was proved to be a woman of most dissolute habits, and her sister to be not over mindful of the injunctions of chastity. Mr. Colliss's testimony was so shaken and damaged by cross-examination, as to prove worse than useless; whilst both the surgeons flatly contradicted their own evidence, and at last seemed very undecided as to the quarter in which the truth really lay.

The witnesses for the plaintiffs were, Mr. Williams, a surgeon, who had attended Scott from 1836 to 1842, during which time he never had occasion to treat him for cough or spitting of blood; Mr. Barnett, a clerk in the "Norwich" office; Mr. Edmunds, an agent, and Mr. Williams a referee, of the "Imperial," all of whom spoke in favour of the man's general good health; and Mr. Wickenden, who expressed his belief that, in 1840, when admitted to the insurance, his chest was not unsound.

The jury found a verdict for the plaintiffs.

Had the witnesses for the defendants been more competent to the giving an opinion upon the subject at issue, and had certain of them been of better character, it would have been no very easy matter for the jury to decide which party was in error. The testimony, *pro* and *con*, was as opposing as it well could be, but the least exceptionable evidence seemed to be on the side for which the verdict was given.

The pathological question, however, may be raised, what is the probability of the man's lungs being to some extent unsound at the time of his insurance? Not in the possession of further facts than were elicited at the trial, of course we are not competent to speak beyond the licenses of surmise; and we only entertain the subject at all, because of the important relations which it holds to a delicate and debatable point in practical medicine, and to the system of life insurance generally.

Taking it for granted that the man had been occasionally in the habit of spitting blood prior to his insurance, ought that fact, *per se*, to have disqualified him? Certainly it is a symptom of a very suspicious nature, as the company seemed to believe, for upon it mainly they raised their objection; but it is not *necessarily a serious one*. A man may spit blood copiously and frequently without any disease of his lungs existing. It may trickle from the posterior nares into the throat, and there exciting irritation, cause itself to be coughed up as though the tracheal or bronchial membrane had discharged it. It may be produced from the fauces themselves as a result of local congestion, in which case it is generally attended by a cough, which, to a young practitioner, often gives it a character of consequence. It may proceed from the palate, the lining membrane of the mouth, or the gums, and to an unpractised observer have a seeming of seriousness. Nay, simple turgescence of the blood-vessels supplying the lining membrane of the air-passages or air-cells, may be the origin of a harmless hæmoptysis, with which tuberculisation of the lungs, or even a tubercular diathesis, has no connection whatever. Add to these the frequency with which hemorrhage from the lungs and neighbouring parts is vicarious of sanguineous discharges from remote organs, as in the case of suppressed menses, piles, &c. And we find that a spitting of blood is not usually indicative of pulmonary mischief, unless accompanied by other signs and symptoms which unequivocally mark organic lesion. And though the very existence of hemoptysis would make one particularly cautious in examining a candidate for life assurance, yet *per se* it is no authority for his rejection. We have known men spit blood for years without any attendant organic mischief, and at last be rid of the trouble without any injury following. In cases such as these, the duty of the examiner is to discover the source of the discharge, and to learn whether or not it be connected with local or constitutional disease. This, of course, can only be learnt by a careful analysis of coexistent symptoms, and by the particular means which physical diagnosis places within his reach. Auscultation and percussion should be mainly trusted to in determining whether a subject of hemoptysis have lungs free from cavities, and tubercular or other degenerescence. Without such forms of exploration, skilfully used, we should be inclined to attach little importance to an opinion which pronounced any man's respiratory apparatus to be free from injury.

In the case of Scott, the probability is that, at the time of his admission to insurance, his lungs were not the seat of mischief, because there was a great deal of corroborative testimony to prove such to be the fact; but in our opinion, the evidence of a single individual who had carefully stethoscopised the man, would have weighed more than all the rest put together. Such evidence, if coming from a competent source, could not be appealed against, and its value should make medical examiners particularly careful to trust largely to physical diagnosis in determining the fitness of candidates for life insurance.

Another striking feature in the case in question is, that the man actually did die consumptive, and his lungs were found to be extensively diseased after his death. The evidence here, however, is somewhat vague, and we are left to conjecture, how recent or how remote might have been the occurrence of the disease which proved fatal. One practitioner expressed it, as his opinion, that the ailment was of long standing, and another inclined to the opposite opinion. It is by no means uncommon to find pulmonary phthisis run a very rapid course, especially in individuals who, like Scott, had experienced a reverse of circumstances, and in consequence been sufferers both in body and mind. In such subjects, grief and starvation will generate a tubercular diathesis in a constitution previously free from it, and a few weeks be all the time necessary for engendering the seeds of phthisis, and completing their work of destruction. But in such cases we find in the lungs all the evidences of recent disease. The tubercular matter is usually infiltrated, and accompanied often with signs of inflammatory action or sanguineous congestion. If the tubercles be scattered, they are not strongly adherent to the pulmonary tissue, and are not themselves indurated, or in any degree cretaceous. If there be cavities, they are usually unprotected by membrane, or if lined by one, it is readily detached from the structure it covers, and itself is tender and easily broken down under the fingers. These are the post-mortem appearances which chiefly indicate consumption to have run its course quickly. We could have wished that in the case in question, the specific appearances had been notified, so that we could have confirmed in our own minds the belief we have that the progress of the disease was rapid.

We have dwelt thus upon two particulars connected with this trial, both, because they are interesting as pathological items to the profession generally, and are not unlikely to be of future service in disputed questions concerning life insurance.

At all events, though the issue of the trial was in favour of the medical authorities, it shows how great caution is required in certifying to a man's physical health. It is a duty, in whose discharge the medical referee cannot be too scrupulous, for he may inadvertently, and very unwillingly, become the author of mischief. So numerous are the frauds attempted to be committed against insurance companies, that it is no wonder they should be so active in seizing every opportunity of protecting themselves from imposition. Were they to be indifferent to any deception that might be intended towards them, they would open an avenue for such trickery as would soon operate to their sacrifice.

People who insure their lives, should go upon a broad principle of honour, and with-hold from their medical examiners none of the facts which it be

comes them to detail; and the examiners themselves should take nothing for granted, but trust mainly to the testimony of their own senses, scrupulously exercised. These only are the means by which future difficulties and disputations may be avoided.

EXTENSION OF THE "JOBBING" SYSTEM.

We have recently laid bare the gross case of a "jobbed" examinership—a case which must excite the indignation of every honest man wishing well to science and the due honour of its deserving cultivators. Nor is it our fault if the individual who, giving way to this disgraceful piece of "simony," has now to bear the responsibility of being its principal actor, should fancy that our attack was animated by personal spleen rather than by a thorough disgust at a system which must ultimately bring all the higher representatives of medical science into universal contempt. Mr. Liston thinks himself aggrieved: this is exactly our opinion: but the grievance is not from us. He is paying but the penalty of bad companionship, and its effects bad acts. The source is traceable to those who have made him a truckler for office—a purchaser of scientific distinction on the well known principle by which Giessen diplomas are purchased—a principle which, if extended beyond the circle of the Council, would place the most worthless person in the Profession—aye, or in the kingdom—in the Court of Examiners. As Mr. Liston allowed himself to be *bargained* into place—as he gave up half his fees as the price of securing the other moiety—what security have we that Mr. Liston's clerk—we will go further, Mr. Liston's dissecting potter—may not be smuggled in next on the same pecuniary principle? "Those who win may laugh." Mr. Liston has got the object of his barter—why, therefore, is he angry with us for announcing his mercantile success? Must Mr. Liston's imitative mania, in the eleventh hour of life, not only force him to take a leaf out of Syme's book of Job—the master enacting the same scene of scientific huckstering that he had so stoutly condemned in his apprentice—but also imitate the Edinburgh Professor in his peevish sensitiveness at the exposure of his scientific pliabilities? It is very well among the lower animals for the bear to enjoy the discomfiture of the ape, while the simian beast shall be prohibited the expression of a reciprocal feeling; but among specimens of a somewhat higher civilisation—among professors of surgery—better views of distributive justice ought to prevail. And if Mr. Syme may now justly retort on his old accuser, *à fortiori*, we, who have always condemned scientific jobbing in all persons, may claim a free enunciation of our censures.

The system spreads. We have laid bare the system of domestic economy, including the sale of chairs, which has given such brilliant illustrations to scientific progress in the Academy of James the Sixth, the "far-famed" and highly flourishing University of Edinburgh. Thence we marked its progress, as a filthy bird of Northern origin, to the dark recesses of the Council Chamber in Lincoln's-inn-fields. Another flight—alas! too speedy—brings us to the University College in Gower-street—a job and pension again proclaiming its ominous presence. Professors of physiology seem to be influenced by the proximity of "*jobbing*" professors of surgery. The two scientific importations from Edinburgh—worthy Scotchmen both—stood shoulder to shoulder in collegiate bargainings. As though physiology had taught doubts of the stability of the Gower edifice, a new diplomacy, of immense sagacity, has been displayed by one of its professors, and a provision of a most extraordinary kind secured to him, quite independently of whatever may be the fate of the institution itself.

We can understand that institutions may struggle on, daily losing reputation—failing yearly in funds—as useless to their proprietors as unpopular with the public—and yet hold a place among the scientific bodies of the metropolis; but we will not believe that any institution can survive the pensioning at the expense of the general fund, and independently of all contingencies, of any gentleman, however respectable, merely on the ground that he has influential political supporters. But this is a subject too important to be dispatched in haste. We shall speedily recur to it.

We understand that a fixed annual income of about six hundred pounds, secured independently of all contingencies, has been voted to William Sharpey, M.D., F.R.S., Professor of Physiology, by the ruling committee of University College.

INSURANCE OFFICES AND FEES TO MEDICAL MEN.

We are hearing constantly of the poverty of the Medical Profession. Every day brings before us deplorable facts showing that the *res angusta domi* is urging one unfortunate practitioner after another to biddings after business discreditable to themselves and debasing to the reputation of their order. The evil, thus widely felt, and deeply lamented, is not lessening. It rather increases. The poverty that is declaimed against is the stimulus to its augmentation. There is an "appetite" of poverty, "growing on what it feeds." We throw the fault on society—on the laws—on our own corporations—on Government. Are we right? We may charge on them that they lend us no helping hand; but how consistently do this, when we lend ourselves none? Where is the organisation among ourselves to meet injustice by resistance?—to ward off imposition by combination?—to weaken individual temptation by aggregate support? Why is it that individually we are in isolation and antagonism? Why is it that no man is sustained in making a stand against wrong by the consciousness that every brother member in similar circumstances will do the like? How happens it that an honest man is always feeling that a sacrifice to the honour of his Profession is nine times in ten but a transfer of his practice to some less scrupulous neighbour? The fact is, we do nothing for the interests whose injury we lament. There is no good understanding among us, through our own want of activity and good feeling; and this want of good understanding can lead to nothing but an increase of that trade competition and social misery which threaten the destruction of the gentlemanly standing of our calling.

Does any man fancy for an instant any member of any other profession would submit to the injustice which too many medical men are meekly receiving from insurance companies? Imagine the directors of the Globe, or Atlas, or Hercules, or Achilles societies, asking Mr. A., the attorney, to note precisely, for nothing, the nature of the assets, or Mr. B., the surveyor, to describe minutely, for nothing, the houses of a certain X. Y., who is thinking of a negociation with the company—what would be the response? Not a word is necessary to describe it. Why are we—gentlemen of a learned profession—so much less independent? Why are we—complaining of our poverty—so far more generous?

Mr. Self, of the Commercial-road East, has sent us a correspondence between himself and an insurance company, which throws a very desirable glare of light on this displeasing deformity, and, while recognising the usefulness of the illustration, we are gratified to notice, with our warm admiration, the public spirit displayed in reference to it by our correspondent. Here is his letter to us—

Sir,—Having frequently read your admirable remarks on assurance office fees, I beg to send you a report of a correspondence which has taken place between myself and "The Scottish Widow's Fund Assurance Office," showing the estimation in which the profession are held by these gentlemen.

The following letter is an answer to their thirteen questions:—

Letter No. 1.

Sir,—I acknowledge the receipt of your long list of questions respecting the state of health of Mr. F. La M., and beg to say, as the information I am required to give is to direct you how far it is likely either to be a matter of profit or loss, I am somewhat surprised how you can attempt to gain information so valuable, without the trifling consideration demanded by the profession; and think, if you require any certificate beyond that of your own referee, you have no right to ask it of a stranger, without a fee, as it is solely for the direction of the assurers, and not for the satisfaction of the assured. I, therefore, under such circumstances, must decline answering, unless you comply with my demand of one guinea.

I remain, Sir, your obedient servant,
Wm. Self.

December 6th, 1845.
To Hugh McKean, Esq.

The following is a copy of reply, *verbatim et literatim*:—

Scotch Widow's Fund Assurance Office,
7, Pall-Mall, London, Dec. 6, 1845.

Sir,—In acknowledging the receipt of your note this morning, I beg to correct the strange error you have fallen into, in supposing, for a moment, that the directors of this society are to be guided by your opinion in the matter of *profit or loss*. On reference to the paper in question, you will find, on a more careful examination, that it is at the request of the applicant for assurance, and *not* of the society, that you are called on to answer the queries referred to. The fee demanded by you for answering these queries must, therefore, be a matter of arrangement between you and M. La M.

I am, Sir,
Your obedient servant,
H. McKean.

William Self, Esq.

Letter No. 2.

Sir,—I acknowledge the receipt of yours, of the 6th inst., and beg to assure you that I *have* made a more careful examination of your statements, but am sorry to say I shall ever remain in the dark, unless I am enlightened by you on three points:—First, Why am I asked, unless the directors *are* "to be guided by my opinon in the matter of profit or loss?" Secondly, Why is it you have "fallen into the strange error," to head your medical report, "Questions by the Directors," if they *really are* at the sole desire of the party to be assured? And thirdly, Why is it that you put such a question as the thirteenth, if it is not for the *satisfaction* of the directors? viz., "State any other circumstances within your knowledge, with which you may think the directors ought to be acquainted, to enable them to judge of the *eligibility* of the proposed insurance?"

I am, Sir, yours, &c.,
William Self.

December 8th, 1845.
To Hugh McKean, Esq.

I beg further to say they took the responsibility on themselves (which is as it should be), by accepting a third party, *not* professional. I have pursued this present course ten years, and do not know of any instance where I have failed to satisfy my patient of the unjust attempt to rob us of a portion of our means of living. I cannot but draw your attention to the word "eligibility" in the last paragraph, and too strongly reprehend the course recently pursued by some offices of shifting the questions

off their shoulders, pretending they are at the "request of the applicant." I am very sceptical on some correspondence being so "strictly confidential" as they would lead us to believe, and here forward you the name of a medical friend, whose unfavourable medical report was actually *given* to the applicants (the office I do not now remember). The result, as you may imagine, was his dismissal as medical attendant.

I remain, Sir, yours faithfully,

WILLIAM SELF.

8, Lucas Place West, Commercial Road East.
March 24, 1846.

Mr. Self's conduct deserves to have its best encomium—general imitation. But to secure this object, more than our encouragement is necessary. The voluntary associations should take up the subject. In another article we will show in which way.

THE UNIVERSITY OF EDINBURGH.

In the letters of Mr. J Briggs on the abuses in the above institution, the statement was made that, among other misdeeds committed, Mr. Mackenzie, the anatomical demonstrator, had been unceremoniously expelled from his office. On the 16th February, Mr. Mackenzie forwarded to us for Mr. Briggs a letter demanding proof of the statement or a retractation, Mr. Mackenzie adding, "so far from 'expulsion,' I voluntarily resigned, after twenty-seven years' uninterrupted hard duty. This step I adopted contrary, be it observed, to the earnest wishes of Dr. Monro himself, and entirely in consequence of the state of my health. I suspect, however, that I understand the incidental cause of the misconception into which you have been led; and, if I be correct in my conjecture, then, and in that supposition, permit me to tell you that you have formed a very erroneous opinion of me, if you think so poorly of me as to believe seriously that I would surrender a good situation for anything so contemptible as the mop of a monkey, or the hiss of a serpent. For my part, I have nothing to conceal in this connection, and I am free to make any explanations on any points connected with my resignation." Not knowing the precise address of our correspondent, Mr. Mackenzie's note did not reach him till lately, when accident opened to us a channel for its transmission to its destination. We have received a letter from Mr. Briggs, stating that no offensive idea was intended to be conveyed against Mr Mackenzie, and that the expulsion was cited as an instance of the absurd policy of the notorious town council. It proceeds—

"You must also have remarked that not one allusion was made to the correspondence between the council, Syme, and yourself, nor to the mysterious conference at Sir Jemmy Craig's, &c., on some of which points I might have enlightened the world most marvellously. I am well aware that you were not expelled (nor indeed were Cormack, Bell, Home, &c., from their respective places), and had I the matter to re-write, I should, in compliance with your wishes, show you how clearly I understood the distinction between the two words expulsion and resignation. I am aware, also, that had you not taken Dr Munro under your protecting wing, the university must have closed, unless the professor had retired—an event as unlikely as a fall of the sky I am as intimately acquainted with these matters as I am with the facts and the getting-up of the coalition in October, 1842," &c.

The controversy has extended to so great a length, that we should not have made even this slight reversion to it if there had not been involved a point connected with the personal reputation of a brother anatomist.

THE ASIATIC CHOLERA.

This mysterious scourge is again at its work in Persia, whither it travelled by the route of Khorassan At Herat, Bokhara, Teheren, Ispahan, and Mechid the deaths have been very numerous. At Mechid a third of the population were carried off. The only town of importance that has escaped is Tabres, now one of the principal cities of Persia. This exception is the more remarkable, that Tabres is visited by more caravans than even Ispahan. The various theories that exist on the etiology of cholera, and the unquestionable obscurity that surrounds it, makes it desirable that each movement of the enemy should be carefully noticed by the medical journalist.

TRANSACTIONS OF LEARNED SOCIETIES.

WESTMINSTER MEDICAL SOCIETY.

Meeting of April 4th, 1846.

Mr Hancock, President, in the Chair.

A communication by Mr. Fisher, F.R.C.S., entitled—"A Case of Insanity of Fifteen Years' Standing, with Effusion beneath the Dura Mater, and the Formation of a New Membrane," was read.

W. P., the son of a gentleman of fortune, at the age of eight years, when at Winchester School, received a severe concussion by the blow of a cricket bat or ball, followed by an attack of furious insanity the same evening, from which he recovered for a time, but soon after he was brought to London labouring under a relapse, and then came under my care for the first time. He recovered and went into Devonshire with his friends—had another relapse, and was placed under private medical care for a period of eight years. He was then brought to town, and again became my patient, labouring under the same malady. The history given of him during the eight years was: that he had occasional attacks of insanity, lasting two, three, four, and five months, with a considerable lucid interval between each attack. He was then sent a short distance into the country, under my superintendence, for a period of five or six years, and for the last two years and a half to Messrs. Stilwell's excellent establishment, Moorcroft House, Hillingdon. It was remarked that each attack increased in duration and violence, and there was generally a lapse of eight or twelve months between them. He was a fine handsome, healthy, muscular, young man; to a common observer merely weak in intellect, and childish in manner; loquacious, but without delusion; his appetite voracious; he was fond of reading the lighter works of literature; he played well at chess, billiards, and whist, and was capable of great bodily exertion, frequently walking twenty miles a day when in health.

The premonitory symptoms of each attack were marked by fulness of habit, lowness of spirits, sullen dogged manner, and loss of appetite; he became cruel to animals, of which at other times he was fond; when not insane, his general demeanour was marked by kindness. He had a religious turn of mind; would write sermons, and had a most retentive memory. During his insane attacks he would repeat passages from scripture for many successive hours, and quote poetry. When in health he was amiable and kind-hearted; and he was very susceptible of the tender passion. The last attack of insanity commenced in May, 1845, and continued, with occasional intervals of a few days' tranquillity, until the middle of the succeeding December—a period of seven months—when he rapidly recovered, and from extreme prostration he resumed his usual fulness of habit. On the 3rd of January, 1846, his last illness commenced with a violent pain over the forehead, accompanied by a sense of weight, and lowness and depression of spirits. He was cupped, and took calomel, with aperients. On the 5th, vomiting came on, with increased pain in the head. Mustard poultices and blisters were applied to the stomach, and calomel frequently given, followed by relief from sickness; cold lotions were applied to the head. During this period the mind was perfectly clear. On the 9th he became so drowsy that it was almost impossible to rouse him, and when with difficulty roused, he relapsed immediately into a comatose state. When conscious, he complained of severe pain in the head, and all his symptoms indicated great congestion of the brain, for which active treatment was resorted to. On the 13th, the patient was in every respect worse. The right eye turned outwards, and the eyelid was affected with ptosis, the will having little power over it, and the pupil more dilated than the left, but there was not any paralysis of the muscles of the face. On the 17th the symptoms had all been alleviated by cupping, leeching, and the continued exhibition of calomel, and the patient appeared to be improving. On the 20th the right eye had recovered from its paralytic state, and the pain in the head was much relieved, but the coma continued, and he was with difficulty roused to take food and medicine. On the 23rd the mercury appeared to be affecting the gums; the symptoms were slightly improved; he could get out of bed without assistance, and knew the persons about him. On the 26th he changed for the worse, became feeble and slept constantly. He continued slowly to sink, and died on the 30th, at the age of twenty-three, not having been sensible for the last thirty-six hours.

Post Mortem Examination Twenty four Hours after Death, made by the Messrs. Stilwell and myself.

Upon sawing through the cranium, the instrument perforated the dura mater, and two ounces of blood escaped, which was received in a glass, and upon the removal of the calvarium, the dura mater, the pia mater and the tunica arachnoidea, were found highly injected. The whole of the right hemisphere of the brain had the appearance of a bladder of fluid lying under the dura mater, and from it ten measured ounces of grumous blood, containing a clot and some red blood, escaped. The whole of the brain was then removed and brought to town with the calvarium, and examined without minute dissection, by Dr. Marshall Hall, Dr. Sayer, and myself.

The right hemisphere of the brain was rather less in size than the left, and its surface was of a deeper colour than usual. The arachnoid membrane could be distinctly traced, from convolution to convolution, over the whole surface of the cerebrum. No effusion had taken place in either of the ventricles The left corpus striatum, and the left thalamus, were larger than the corresponding parts on the right side. The medullary and cortical substances of the cerebrum and cerebellum were well defined and perfectly healthy. It was suggested that the dura mater should be minutely examined by Mr. Lane and Dr. Sayer, and it was taken away by the latter gentleman; Mr. Lane being out of town, it was without any dissection examined by Dr. Sayer, and the impression on his mind was, that the sinus longitudinalis was in an abnormal condition; that a gradual separation of the laminæ of the dura mater had taken place to the extent of several inches on the right side of the falx, by which a large pouch had been formed, capable of containing many ounces of venous blood. The membrane was returned the same evening, Feb. 1st, and on the 22nd of March, it was very minutely examined and carefully dissected by Mr. Hancock, in the presence of Mr. Hird, Dr. Sayer, and myself. The true nature of this membranous pouch then became apparent, and I am indebted to Mr. Hancock for the following descriptive details of our investigation.

The preparation showed a large cyst formed evidently of adventitious membrane, situated between the parietal and visceral layers of the arachnoid, and extending the whole length of the right hemisphere of the brain, which had been removed together with the arachnoid and pia mater. This cyst also extended from the falx major laterally, to the portion of dura mater covering the outer border of the cerebrum. It did not communicate either with the superior or inferior longitudinal sinus, the former of which had been laid open to prove this fact; neither did it communicate with the lateral sinuses, but appeared to be the result of abnormal action. The bones of the cranium were much thinner than natural, being at no part more than a quarter of an inch thick, but in places consisting of merely the two tables. There was an evident

bulging of the right parietal bone towards its anterior and inferior angle, and there the diploe had been entirely absorbed by the continued pressure of the cyst within. The right half of the frontal, occipital, and the squamous portion of the temporal bone of the same side had been subject to a similar action. It appeared that the whole brain must have been pushed over to the left side, and that considerable pressure had been exerted on the left parietal bone, which towards its anterior and inferior angle was in places almost deprived of its diploe, although not to the extent of the opposite side, neither did it bulge, as in that situation. The left half of the frontal and occipital bones appeared to have escaped this pressure. When the calvarium was measured internally, there was found an addition of half an inch in favour of the right side. The left portion of the lesser wing of Ingrassius with the corresponding anterior clinoid process was reduced to the thickness of a sheet of writing paper, and presented almost a cutting edge.

Cases of the formation of these cysts or adventitious membranes under the dura mater are not of common occurrence; MM Andral and Foville have noticed them, the latter in the eleventh volume of the *Dictionnaire de Médecine et de Chirurgie*, under the head of "*Meningite*;" and other French pathologists, as one of the forms of "*apoplexie des meninges*" Mr. Prescott Hewett, the curator of St. George's Pathological Museum, brought this subject before the Royal Medical and Chirurgical Society, and published cases illustrative of the disease. He did me the favour to show me four specimens put up by Sir Benjamin Brodie and himself in the museum of St George's Hospital; one of these specimens has been there some twenty years. It has been demonstrated that these membranes are supplied with secreting and absorbent vessels, which in itself accounts for the occasional attacks of insanity in my patient. It was always remarked when he became plethoric, that the attack came on, and upon his losing flesh and becoming very thin, his reason returned

The cause during life was considered hereditary, his father having been insane from injury of the brain, by a fall from his horse, two years before the birth of the son. The result of this investigation cannot be otherwise than satisfactory to the family of the patient, as it tends to do away with any impression as to hereditary predisposition to insanity, and takes us back to the accident received when at school as the exciting cause.

*** The morbid preparation, and the attenuated calvarium were exhibited to the society.

Mr. Stillwell described the state of the patient while at Moorcroft House, and confirmed Mr. Fisher's statement respecting the only attack of insanity to which he was subjected while in that establishment. It continued for seven months, and was marked by the usual symptoms of mania. The treatment which was adopted consisted in the occasional exhibition of calomel, the use of mild aperients, and the strict observance of quiet. Morphia could not be borne by the patient.

Mr. Prescott Hewett observed that he had seen many cases in which there were cysts similar to that then before the society. In general there were not present any diagnostic symptoms by which the real nature of the disease could be ascertained, nor was the presence of such a cyst necessarily accompanied by insanity. The symptoms, on the contrary, might resemble those of apoplexy, cerebral softening, or effusion. These cysts were some years since always described as seated between the dura mater and the parietal layer of the arachnoid, but they have since been shown to occur between the two layers of the last named membrane.

Dr. Sayer read a case from the fourth volume of Andral's *Clinique Médicale*, which he considered bore immediately on the case under the notice of the society, and in which, according to Andral, the effusion was located between the dura mater and arachnoid membranes.

Mr. Hind, Mr. Streeter, and other members of the society made some remarks as to the formation of the cyst, and its general influence on the cerebral functions, after which the further consideration of the case was adjourned till the next meeting of the society.

MICROSCOPICAL SOCIETY OF LONDON.

At the last meeting of this Society a paper from the pen of the Honorary Secretary, John Quekett, Esq., Assistant Conservator of the Hunterian Museum, was read on "The intimate structure of bones in the four great classes of animals, viz., mammals, birds, reptiles, and fishes, with some remarks of the great value of the knowledge of such structure in classifying minute fragments of fossil organic remains."

After alluding to the highly important discoveries made by Professor Owen in determining the affinities of fossil animals by means of the minute structure of their teeth, Mr. Quekett went on to state that in investigating the minute structure of bones he had found that there appeared to be certain characters peculiar to each great class, which could be easily recognised, he had therefore been induced to proceed with his researches in order to verify a mode of determining by microscopic examination the class to which doubtful isolated bones of extinct, or recent animals might belong; [and here it may be observed *en passant* that this acute observer has had an opportunity afforded him, of practically proving the correctness of his theory, by Dr. Falconer the celebrated palæontologist of the Himalaya Mountains, submitting to Mr. Quekett's inspection certain small bones which he had found in the Sivalik Hills, near the remains of the enormous tortoise, twenty feet long, discovered by him, and which were supposed to be the toe-bones of some animal of the same species; but their general appearance not being sufficiently characteristic to enable him to determine this with certainty, he requested the aid of Mr. Quekett without, however, giving him any information for his guidance. This gentleman shortly gave notice that the bones in question, were positively those of a reptile, and most likely of the turtle order, thus confirming the suppositions derived from other evidence of their identity]. In resuming the paper Mr. Quekett described the general structure of bone; after which he proceeded to state, that, upon examining a thin transverse section of bone, with a power of about 200 linear, the Haversian canals are seen to be surrounded with a series of concentric laminæ, together with a concentric arrangement of spider-like looking bodies, which have been termed osseous corpuscles, calcigerous cells, lacunæ, or bone-cells. These bone-cells have little tubes or canals, termed *canaliculi*, proceeding from them, and communicating either with the Haversian canals or with the larger canaliculi of other cells. The average length of these lacunæ, or bone-cells, in the human subject, is the 1-2000th of an inch. They are of an oval shape, and somewhat flattened on their opposite surfaces, and are usually about one-third greater in thickness than in breadth In the bones of birds, the bone-cells are of very small size, and in a transverse section of the Haversian canals may frequently be seen running in a tortuous manner, whereby the concentric arrangement is somewhat altered. In the reptilia, the Haversian canals are few in number, and not so regular as in the two former classes, but the bone cells and their canaliculi, are remarkable for their great length and size. In the bones of fishes, these are certain peculiarities which prevent the possibility of their being mistaken for those of any animal of a higher class. In these the Haversian canals, when present, are of a large size and very numerous, and the bone-cells are, generally speaking, either absent or but few in number, their place being occupied with tubes or canaliculi, which are often of a large size. The bone-cells are of a quadrate figure, and the canaliculi derived from them but few in number, and are readily seen to anastomose freely with the canaliculi given off from neighbouring cells. The bone-cells are very beautifully shown in the thin scales of osseous fishes, in the spines of the *siluridæ*, and in the bony scales composing the external skeleton of the cartilaginous fishes, and in the spines of some of the ray family a peculiar structure may be seen; the Haversian canals in them are large and very numerous, and there are an infinite number of wavy tubes connected with each other in the same manner as the dentinal tubes of the teeth are connected with the pulp.

Mr. Quekett proposes to apply the characters derived from the bone-cells to the determination of the class of animals to which any minute portion of bone may have belonged, for example, the fragment of the bone of an extinct animal. The bone-cells of the mammalia have been stated to be tolerably uniform in size, and, taking these as a standard, it will be found that while the bone-cells in birds fall short of that standard; those of reptiles are very much larger, and those of fishes are so entirely different from the three others, both in size and shape, that they cannot for a moment be confounded with either of them. Thus, then, the distinction between the minute structure of the bones of reptiles and of fishes, and those of the other two classes, is very clearly established, the only difficulty is in determining the difference between that of the bones of mammals and of birds. The chief distinction here is the relative size of the bone-cells, and to this the eye very soon becomes accustomed by practice. A transverse section of the bones is also to be preferred for comparison, as the length of the bone-cells is always greatest in that direction.

The author then stated that anatomists have long been familiar with the fact, that in proportion to the size of the blood corpuscles, so is that of the capillaries, and of the muscular and nervous fibres; and it would appear that the same thing held good with respect to the bone cells. From the highly valuable table of the blood discs, lately published by Mr. Gulliver, it appears that the blood particles are largest in reptiles, smallest in mammalia and birds, and in fishes of an intermediate size; and it has already been stated, that the bone cells are largest in reptiles, and are much smaller in mammalia and birds; hence it would appear, that the bone cells are subject to the same law as the capillary, muscular, and other systems; and in the advanced stages of the inquiry, it may possibly turn out that if one or other of these systems be known, that the size of the others may be readily inferred.

Mr. Quekett concluded his highly interesting and most important paper, by remarking, that however different the size of animals of any one class may be, precisely the same structure of the bone is found. Thus there is no perceptible difference in the intimate structure of the bones of the enormous iguanodon, (100 feet in length) and in those of the smallest lizard, or between that of the bones of the mastodon, as compared with the structure of those of the mouse, and hence arises the value of these microscopic characters, in determining the class to which the animal (whether recent or fossil), whose bone may be examined, has belonged.

MISCELLANEOUS CORRESPONDENCE.

NON-PAYMENT OF MEDICAL WITNESSES.

(To the Editor of the Medical Times.)

SIR,—I beg to present you with the accompanying statement, not for the sake of trifling with your attention on an individual hardship, but in the belief that you will consider it important from the relation which the subject thereof bears to the interests of the profession, and consequently be induced to publish it, or do that which would be infinitely more efficient—notice the subject yourself.

Very obediently yours,
P. HALFORD.

1, City-road, Finsbury-square.

About nine or ten weeks ago a man was brought to me in a state of unconsciousness, with an extensive contused wound on the right side of the head, and with great redness and swelling under the opposite ear. The redness and swelling were produced by a blow, which knocked the man down, threw his head in contact with the curb-stone, and thereby produced the wound—probably, also, the concussion. These injuries having been occasioned wilfully and unjustifiably, the case was brought before the police magistrate, who, desirous of being satisfied touching the man's ultimate recovery, and the probable duration of his illness, before finally adjudicating on the matter, had occasion to remand the case several times. On two of these occasions (having been informed by the police that a certifi-

cate would not be sufficient) I waited in the police-court from mid-day till evening to give evidence, and from ten until four on a subsequent day, to repeat the evidence previously given. Here, the magistrate considering his power too limited to enable him to punish the prisoner adequately, sent the case to the sessions, where his worship also bound me to appear under a penalty of £20. Of course I attended and was compelled to wait—on the first day from ten until six; on the second day from ten until five, before the grand jury found a true bill; and on the third day from ten until four, when the prisoner was convicted. I now come to that point of the subject which relates to the compensation of medical witnesses, and this, I conceive, affords a curious illustration of the inconsistency of the law on the matter. The trial being over, I applied for expenses for loss of time, &c., but as I had been previously informed that the adoption of a mere technicality would prevent their being allowed, I did so—more, perhaps, as a matter of principle than for the sake of the money. I applied personally to the police magistrate at the police-court and to the judge at the session, when they replied that the law left them without control, or the expenses should have been most readily allowed in such a case. Now, it seems that the title to compensation hinged upon a reply to a question which, without any great impropriety, might have been answered either one way or the other—viz., "was it the blow which the prisoner first struck that produced the mischief?"—or "was it the 'fall' which the blow produced that did it?" Now, although the reply was that I believed the fall to have been the most immediate cause, yet an adverse witness might, and, perhaps, conscientiously, have deposed that the swelling and redness occasioned by the first blow must have required so much violence for their production, that the concussion had, in his belief, resulted immediately from this blow. And when it is considered that did the evidence of the witness go to prove the first blow to have directly produced the mischief, the case would constitute one of felony, in which the expenses would be allowed—whereas, did it only go to show that the fall consequent on the blow produced it, the case would constitute one of assault only—in which the expenses would not be allowed—I think it must be admitted, Mr. Editor, that the law is somewhat too complimentary to the conscience of a witness in assuming that the premium it offers to seduce it will never be accepted on the terms. So much, Mr. Editor, for the law of the matter, which, so far as the propriety of the distinction it makes between felony and assault for the purpose of measuring guilt goes, it would be presumptuous in me to question. But, that such distinction should be equally wise, just, or politic as a test of the value of a witness's services or time, by no means necessarily follows. In short, if that portion of the subject which relates to the compensation of medical witnesses be correctly stated, not only myself, Mr. Editor, but, I believe, most surgeons, would feel obliged by your sentiments on, and exposition of, a law which, after extorting six days of a man's time from him, professes to manifest its justice by awarding him full compensation if the case be proved one of felony, and refusing the least compensation if proved one of assault only; and this, too, in cases where (as far as relates to a just title to compensation) this palpable distinction is founded on the perfection of an equivocable difference. The only questions that the subject admits of appears to be—"Is the law just in denying compensation to a witness in the one case—is it extravagant and capricious in granting them in the other—or does it regard it to be more expedient, more conducive to the safety and welfare of the public, to proffer compensation for the exaggeration of crime?"

*** The abuse here properly stigmatised deserves, and shall receive, further notice.—Ed.

The first meeting of the Western Medical and Surgical Society was held at the Western Grammar School, Alexander square, Brompton, on Wednesday evening last, when the chair was filled by the president Sir James Clark, Bart. A large number of the most influential practitioners in the neighbourhood attended.

GOSSIP OF THE WEEK.

Obituary.—Died at Yeovil on the 22nd of March, in the 71st year of his age, Maitres Lambe, Esq., surgeon. On the 1st inst, aged 39, George Bernard Corfe, Esq., surgeon, and coroner for the borough of Southampton. March 30th, at the Royal Barracks, Carlow, John Maharg, surgeon, Esq, 70th regiment, in the 43d year of his age.

Naval Medical Association.—A meeting was held on the 18th of December, 1845, at the Royal Naval Hospital, Bermuda, Dr. Evans, *Deputy Medical Inspector*, in the Chair to promote the formation of a medical association, embracing in its constitution all the Naval Medical Officers. The medical officers of the West India squadron have shewn a laudable zeal for the advancement of their branch of the profession; and if we consider the many opportunities afforded to naval medical men for acquiring information, there cannot be a doubt, if the praise-worthy object be carried out, that many of the service will discover a new field for exertion that cannot fail to result in their own improvement and the benefit of science.

Lunatic Asylum for Manchester.—In consequence of the necessary enlargement of the Manchester Royal Infirmary now in progress, it has been suggested and very properly, that the wards hitherto occupied by lunatics shall be given up to the general purposes of the infirmary, it being most desirable that this hospital should be as complete as possible for the rapidly increasing population of this large manufacturing town. The lunatics have therefore been removed into private asylums during the erection of a commodious hospital for their reception, the building of which will immediately be proceeded with on a plot of ground of about thirty-seven acres, in Stockport Etchells, near the Cheadle station on the Manchester and Birmingham railway, which has just been purchased at the cost of £3,500.

Royal College of Surgeons of England.—At the examination on Tuesday and Thursday last for the fellowship of this college, only six candidates presented themselves.

Newcastle Infirmary.—An appeal is about being made on behalf of this excellent institution (established nearly a century ago), in consequence of the utter inadequacy of the accommodation at present afforded by the infirmary for the rapidly increasing necessities of the town, it is proposed to increase the size of it, no addition having been made to it since 1830, when a third story was added for syphilitic patients, and the number of beds amounted to one hundred and fifty; since then no increase in its accommodation has taken place, notwithstanding the enormous increase in the population, the consequence is that patients are frequently sent away for want of room.

Mr Herapath, the celebrated analytical chemist of Bristol, met with a serious accident last week. While operating upon some fulminating silver, it suddenly exploded, and burned his face so seriously that for a time it was feared he would be deprived of the sight of the left eye at least. He is progressing favourably.

Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity.—A half-yearly General Court of this Society was held on Wednesday the 1st inst., at the Gray's Inn Coffee House, Holborn, Martin Ware Esq. V. P. in the chair. On reading the minutes it appeared that two very gratifying benefactions had lately been received. One of these was a legacy, announced by T. A. Stone Esq, of fifty pounds bequeathed by the widow of the late Matthew Baillie Esq., formerly President of the Society, through the liberality of William Hunter Baillie Esq, son and sole executor of the testatrix, this sum had been received free of legacy duty. The other was a donation, presented through Sir B. C. Brodie, Bart, of fifty guineas from Lord Denman. His lordship it will be remembered is the son of the late Thomas Denman M.D., who was one of the original founders of this Society. On the recommendation of the court of directors it was unanimously resolved, that William Hunter Baillie Esq., be elected an honorary member, and that Lord Denman be invited to become a vice-patron of the society. The annual dinner is to take place next Saturday the 18th inst., at the Freemasons' Tavern, and the Chairman of the Steward's Committee, Mr. Propert, drew attention to the importance of *notice being given* by those who intend to be present. The arrangements have been made in the best possible manner, and a full attendance of the members and their friends is expected.

Mr. Liston's paper, containing the details of the late Mr. Seton's case, will be read at the next meeting of the Royal Medical and Chirurgical Society, on the 14th instant.

Curiosities of Medical Literature.—Dieffenbach, of Berlin, entitles the plastic operation for the cure of lachrymal fistula by the unnaturally elongated cognomen—Dacryocystosyringokatakleisis. The mere attempt to utter such a lengthy combination of harsh sounds is enough to dislocate the jaw.

Promotions.—Assistant-Surgeons—S. Livesay, M.D, J. Belcher, M.D., E. Groves, J. W. Roberts, J. Clarke, W. L. Methven, C. T. S Kevern, T. J. Graham, J Campbell, M.D, H. Trevan, M.D., G. Whitmarsh, A. Slight, R. Gregor, and W. Bateman, to the rank of surgeon.

Appointments.—Asst.-Surgeon J. C. Austin, to the Caledonia.

On Monday, Dr. Davies was unanimously elected one of the Physicians to the Bath United Hospital, in the room of Dr. Barman, resigned.

Queen's College, Birmingham.—The Reverend and Worshipful Chancellor Law, the Vice-President, has taken up his residence in the College, in order personally to superintend the proposed extended system of Collegiate Medical and Surgical Education. The Reverend Gentleman has offered to the resident students the following munificent prizes, viz.—£50 to the student who may carry off four medals; £30, three medals, £7, two medals; £5, one medal. William Sands Cox, Esq, has also gone into residence in order to assist the council in carrying out the important arrangements.

War-Office, April 3rd—16th Light Dragoons Williamson Evans, M D, to be assistant-surgeon, vice Stephens, appointed to the 10th Light Dragoons. 24th Foot Surgeon George Kincaid Pitcairn, M.D., from the 19th Foot, to be surgeon, vice Lorimer, who exchanges. 19th Foot Surgeon William Lorimer, from the 24th Foot, to be surgeon, vice Pitcairn, who exchanges. 84th Foot Surgeon John Marshall, from the 65th Foot, to be surgeon, vice Daniel Armstrong, who retires upon half-pay. Assist.-Surgeon John Edward Stephens, M.D., from 16th Light Dragoons, to be Assistant-Surgeon.

MORTALITY TABLE,

For the week ending April 4, 1846

Causes of Death.	Total.	Average of 5 summers	Average of 5 years
All Causes . . .	1028	1080	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	169	183	188
Sporadic Diseases—			
Dropsy, Cancer, and other Diseases of uncertain or variable Seat . . .	109	115	101
Diseases of the Brain, Spinal Marrow, Nerves, & Senses	182	169	157
Diseases of the Lungs, and of the other Organs of Respiration	316	363	294
Diseases of the Heart and Blood-vessels . . .	30	30	27
Diseases of the Stomach, Liver, and other Organs of Digestion . . .	90	69	72

THE MEDICAL TIMES.

No. 312. **SUMMARY.** April 18.

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

(From our own Correspondent.)

ACADEMY OF SCIENCES.

Meeting of the 6th April, 1846: M. Mathieu in the Chair.

Intermittent Fever: by Dr Durand (of Lunel).—The noxious influence of marshes may be referred to a threefold cause—putrid emanations, damp, and heat. The depressive action of the two last-named agents requires no demonstration; it is admitted by all that putrid animal matter evolves ammonia; vegetable matter, in a state of decomposition, yields, on the contrary, alkaline products. In marshes, we find both animal and vegetable substances in a state of putridity, and the recent dew collected over bogs is found to be acid (Moreau, 1828); when preserved some time, on the contrary, it is alkaline (Vauquelin: Analysis of the Dew of the Pontine Marshes). The marsh miasma acts, therefore, in the first place, as a direct sedative of the circulation, in virtue of its alkaline properties, and, at a later period, by the disengagement of negative electricity, when acid products are evolved, tends still further to diminish the natural excitement of the blood—an electro-positive fluid, according to Bellinger and Matteucci.

Valvular Patency of the Orifices of the Heart, by Dr. Parchappe.—Dr. Parchappe communicated to the Academy a very long memoir, the substance of which may be given in a very few words. 1. Dr. Parchappe does not believe that the order of the contractions of the heart is ever interverted, so long as the blood continues to circulate through its cavities. Even after the heart has been separated from the body, the contraction continues for a certain time to be propagated with regularity, from the auricles to the ventricles. 2. Valvular insufficiency is not by any means so common as it is generally supposed, and the method usually employed, in order to ascertain if the aortic valves, for instance, are sufficiently flexible to close the orifice of the artery, namely, pouring water down the aorta, is not, in any case, satisfactory, on account of the difference of weight between blood and water.

Atomic Weight of Uranium; by M. Peligot.—M. Peligot had assigned 750 as the representation of the atomic weight of uranium. Professor Berzelius had fixed upon 800. M. Peligot forwards, on the same subject, a long memoir, in which his own results are confirmed. The oxalate of uranium obtained by several methods, and purified by repeated crystallisation, has given results varying between 745 and 753. Seven analyses of the acetate have given, as a mean term, 750. This number is the exact produce by 60 of the representative of the atomic weight of hydrogen—a circumstance which illustrates once more the great law laid down by Dr. Prout.

ACADEMY OF MEDICINE.

Meeting of the 7th April, 1846, Dr. Roche in the Chair.

The Plague.—On being asked when the practical conclusions of the report on the plague may be expected to be communicated to the Academy, M. Prus stated that they had not yet been unanimously agreed to in the commission, but that very little further delay would take place.

An Essay on the History of Medicine and Surgery, in Greece, before Hippocrates, by Dr. Malgaigne.

Many questions relative to the state of medical science previously to the birth of Hippocrates have been hitherto unanswered, or have been answered in a manner but ill agreeing with historical truth. As a striking illustration of this assertion, M. Malgaigne instances the generally received opinion that medicine and surgery were first cultivated in the temples, and by the priests of Esculapius. This opinion, comparatively of recent origin, had not yet been spread in the days of Galen, who professed that the practice of medicine was at first confined to one family—the descendants, not the priests, of Esculapius. Reference to ancient historical documents shows that Galen, though less far from the truth than modern historians, still laboured under a strange mistake, and that surgery or medicine were at no time the heirloom of one caste or of one family. Before entering upon his subject, Dr Malgaigne thinks it necessary to state how he has been led to conclusions differing from those generally adopted on this subject. A correct picture of any epoch cannot properly be drawn from the testimony of succeeding ages, and the safest road to the truth lies in the evidence of cotemporaries, or, at the farthest, of the succeeding generation, who may naturally be supposed to possess accurate information of events still recent. For the portraiture of the heroic, and what may be justly called the *middle ages* of Greece, one author (Homer) alone must be consulted, and his isolated situation gives his narratives additional interest and importance. Herodotus, who read his history at the Olympian games, in the year 456, B.C. (four years after the birth of Hippocrates), furnishes the most valuable documents for the history of the century which preceded that of the Oracle of Cos, and, in proportion as we draw nearer to Hippocrates, fresh authorities crowd in—Thucydides, Xenophon, Aristophanes, Plato, Ctesias, and Hippocrates himself, whose cotemporaries they were. Any attempt to separate the origins of medicine and surgery has hitherto proved abortive. The succession of events being impartially examined on this point, it becomes evident that the first physician, prevented by religious prejudice from attending to medical therapeutics, practised surgery exclusively, and formed a numerous class of practitioners, on whom the care of internal diseases naturally devolved when the interdiction was raised; and as, in reality, the two professions were never distinct from each other in Greece, it is easy to understand how, in this paper, more specially consecrated to the history of surgery, the author has found himself under the necessity of adverting also to the progress of medicine. In Dr Malgaigne's former researches, it has already been shown that, in the time of Homer, there was not, nor could there be, any internal pathology. Wounds alone were attended to, and the ιατρος of that day doubtless corresponded to the surgeon of ours. It is also worthy of notice that the healing art, limited as it was, was then studied and practised only in Greece and Egypt. In the Odyssey (lib. iv, 232) the Egyptian physicians are mentioned as surpassing all others in skill. They were also numerous in Greece, but, strange to say, no trace of surgeons can be found in the Trojan host, nor amongst the allied nations. Arrows and splinters of lances were extracted by the companions of the wounded Trojans, and cures were looked upon as the result of the interference of the gods. So late as in the days of Herodotus, the kings of Persia, those powerful monarchs of the East, were obliged to borrow their physicians from Egypt or Greece, and Hippocrates himself asserted that the barbarians had not then any physicians. Surgery may, therefore, be traced in Greece to a remote origin, and it is not uninteresting to find the study of medicinal plants in female hands. Nestor recals, as a recollection of his earliest youth (Odyssey, lib. xix, 455), the fair Agamede, "who knew as many remedies as are produced on the entire surface of the earth." This is a first feature of resemblance with our middle ages, when the wounded knight was nursed by the castellan's lady. On the field of battle we find, in our old records of chivalry, that enchanters supply the place of surgeons. Guido de Cauliaco reports that in his day, the men-at-arms, Teutonic knights, and other followers of war, dressed all wounds with conjurations and draughts. These conjurations we find in high repute during the youth of Ulysses. That prince's thigh was severely injured by the tusk of a boar, and the sons of Autolycus, his uncle, skilfully bandaged the limb, and arrested the hemorrhage by incantations (Iliad, lib. iv, v, 190). Such was the origin of the scar by which he was afterwards identified. The first surgeon mentioned by Homer was Chiron, whose pupil, Esculapius, is nowhere in Homer referred to as a god. From Chiron, Achilles received instruction in the healing art, and imparted it to Patroclus. Esculapius educated his two sons, Machaon and Podalyrus; but, besides the school formed by Chiron, many other surgeons flourished amongst the Greeks. Evidence of the assertion may be found in several passages of Homer, but Machaon appears to have enjoyed the greatest reputation for skill. Thus, he is sent for by Menelaus, and dresses that prince's wounds on the field of battle.—(Iliad, lib. v, v. 900.)

If we inquire into the resources of this very primitive military surgery, we find simple wounds dressed with emollient applications. The suspicious looking wound was sucked before it was dressed. Foreign bodies were removed with the sharp instruments (Μαχαιρα). Hemorrhage was arrested by the application of a bitter (doubtless, an astringent) root, bruised between the hands. This was only local treatment. In another passage Homer mentions the regimen. Machaon himself was struck by an arrow. Nestor led him into his tent, where he made him drink a cup of wine, containing scraped goat's cheese and flour.—(Iliad, lib. xi, v. 620.) The recipe may certainly surprise us, and several critics condemn, in such cases, the exhibition of wine; but we must recollect the wound was very recent, and when Larrey exhibited wine to the wounded under his care, and even to those whose limbs he had just amputated, he was, probably without being aware of the circumstance, a disciple of the school of Machaon.

No doubt it is impossible to assert that things occurred at the siege of Troy exactly as they are narrated by Homer, but it is perfectly certain that customs, habits, and everything connected with the exercise of various professions, were described by the poet with the most faithful accuracy. Homer flourished two or three centuries after the siege of Troy, and we may therefore conclude, with a tolerable degree of certainty, that in the ninth century A. C., four hundred years only before Hippocrates, surgeons existed in Greece, but no physician for the internal complaints; that medical art was created by Esculapius, in whose family it did not remain as an exclusive heirloom; and lastly, that the science was not cultivated in his temples, for the simple reason that he was not deified for a long time after that period. Plato, according to Socrates, states that Pindar and the tragic writers are those who made Esculapius son of Apollo, and who asserted he was struck with a thunderbolt for having cured a mortal disease. Socrates carefully adds, he does not believe one word of the story.

The first notions of internal medicine may be conjectured to have been established a short time before the erection of the temples of Esculapius, perhaps two or three centuries before the birth of Hippocrates. Herodotus has left a long account of the adventures of a surgeon, named Democedes, and it contains some points of analogy with the lives of several of our modern surgeons. Democedes was born at Crotona, and settled at Ægina, where he very soon threw the other practitioners in the shade. The following year the Æginetans, anxious to preserve amongst them so learned a physician, gave him out of the public treasury a pension of one talent (£216). The ensuing year the Athenians outbid them, and obtained the doctor's services at a salary of one hundred mines (£360). His renown increasing with his years, Polycrates, tyrant of Samos, attached him to his person, and gave him two talents (£430) a-year. But Polycrates was killed treacherously by Oretes, and all his slaves Democedes amongst them, were transported to Asia. A succession of events useless to record brought him to Susa, where fortune awaited him. Darius in leaping from his horse, gave himself a sever sprain; indeed, as far as we can judge from the text of Herodotus, the inferior extremity of the fibula was fractured. He had at his court the most celebrated physicians from Egypt; but these persons were very clumsy surgeons, and they gave the prince so much pain by the violent manner in which they handled the injured foot, that a violent irritation supervened. The king did not close his eyes for seven days and seven nights. On the eighth day some courtier mentioned the Grecian slave taken with the property of Polycrates. Democedes was accordingly sent for, and in such despatch that he appeared in rags, and with shackles to his feet. Being asked if he knew anything about medicine, he hesitated before he answered in the affirmative. In a precisely similar situation, Ambrose Paré also hesitated to acknowledge his profession. But in antiquity, as well as in the 16th century, princes were in possession of never-failing methods of loosening a surgeon's tongue. Darius sent for instruments of torture, and Democedes immediately complied with his wishes; but, in order to shelter his responsibility, he declared that his knowledge of medicine was extremely limited. He treated his royal patient according to the principles of Chiron, with emollient applications. Sleep returned, the king soon recovered, and his gratitude knew no bounds; but the Egyptian doctors were condemned to be crucified—a punishment which was remitted through the intercession of their successful rival, who was richly recompensed. But he was haunted with the desire of returning to his native country, and having cured Atossa, wife of Darius, of an ulcer of the breast, he obtained from her that she would express a wish to possess Grecian slaves—a desire which Darius endeavoured to gratify by invading Greece. Democedes accompanied the invading army, escaped, and was subsequently married to a daughter of Milo, of Crotona. Thus, the first cause of the invasion of Greece by the Persians was the captivity of a Greek surgeon.

Another Grecian colony soon rivalled Crotona in the excellence of its physicians. It was Cyrena. As to Cos and Cnidus, they were not even mentioned. We must even reluctantly confess that the first appearance of the disciples of the school of Cos on the stage of public life, does not say much in favour of their moral character. Some years before the birth of Hippocrates, a physician from Cos, called Apollonides, went to Persia to seek his fortune, and cured of a severe wound Megabysus, son-in-law of Xerxes. Megabysus having died a short time after, Apollonides continued to attend professionally his widow, Amytis, and being sent for one day to give her his advice for some trifling illness, he had the audacity to inform her that she was labouring under uterine disease, and that her only chance of a cure was in intercourse with one of the other sex. Amytis received the advice with becoming submission, and permitted the doctor to perform his own prescription. Apollonides was soon tired of his conquest, and, having forsaken her, awoke in her breast a violent resentment. She confided the entire transaction to her mother, and obtained revenge. Apollonides was arrested, submitted to atrocious tortures, and buried alive on the day of the death of his implacable enemy. This tragical history is narrated by Ctesias, who afterwards became physician to Artaxerxes. Galen asserts this Ctesias was of the family of Esculapius, and consequently a relative of Hippocrates; but of this assertion no proof whatever has been given; at any rate, Apollonides was never stated to have been an Asclepiad, and therefore the two first Greek physicians mentioned in history, Democedes and Apollonides, did not belong to the sacred family. To these may be added Alcmeon, of Crotona; Acron, of Agrigentum; Herodicus, of Leontium, and Eutyphon, of Cnidus, to whom were attributed the Cnidian Sentences, and who is by no author considered to have been even distantly related to the descendants of Esculapius. Besides these numerous physicians, antiquity could also boast of many quacks, soothsayers, and priests of Esculapius—dangerous rivals in practice, but never in scientific matters.

Let us now examine how medical studies were instituted; what resources were offered to the pupils; what was the nature of their intercourse with each other and with their patients in private practice; and lastly, what was the constitution of military surgery.

There were no medical schools, properly so called. Galen speaks, it is true, of the three great schools of Cos, Cnidus, and Rhodes (which was probably mentioned by mistake for Cyrene); but by the word school Galen meant only an association of physicians, practising under the influence of the same doctrines, and even such schools it would be difficult to demonstrate the existence of previously to Hippocrates. It is sufficient to glance at the Hippocratic collection to form an idea of the incredible number of diverging theories which divided the profession. The pupil desirous of beginning the study of medicine, made choice of a master, to whom he paid beforehand the sum stipulated for his apprenticeship. A passage of Meno is perfectly clear on this point. Another passage of Protogoras shows that Hippocrates was one of those teachers who took pupils for a pecuniary consideration. A proof, this statement may also be found in the celebrated oath, where it is also said that, if the pupil had no money, he was made to sign a written obligation for the amount. It is right not to forget the honourable exception which Hippocrates himself established to this rule. What was the amount of the *fee* to the master? It seems to have depended very much upon his reputation. Evinus, of Paros, received only five mines (£18), and Zeno one hundred (£360). The books were already numerous; it is an undoubted fact that many works of the Hippocratic collection were written before Hippocrates. Oral lectures seem to have been the most common mode in which instruction was communicated.

HOPITAL NECKER.

Clinical Lecture. *Diseases of Nurses and Infants;* By Professor Trousseau.

Sclerema.—The first case to which we will direct your attention, is that of an infant, aged twenty-five days, and affected with induration of the cellular tissue. The mother is dying of what may be called a sort of puerperal farcy; when she came to the hospital, abscesses were forming in the limbs, and a collection of pus had accumulated in the left knee, with considerable pain and febrile excitement. She was improved so much during the few days which followed her admission, by the exhibition of one-twelfth of a grain of calomel every hour, that we thought her saved. Salivation was established at the expiration of the second day, all the morbid symptoms had yielded, and fluctuation could no longer be felt in the diseased joint. Since then a poultice, with leaves of datura stramonium, opium, and camphor, has been applied to the knee, but a sudden relapse has taken place, and her present state leaves us but little hope of saving her life. For several days her infant took the empty breast; the want of proper food, and perhaps his unsuccessful efforts to draw from his mother a sustenance which she could not yield, disordered the gastric functions, caused diarrhœa and vomiting, which milk and magnesia have to a certain extent allayed, but yet the weakness of the child continued, he grew gradually colder, and on touching his body this morning (April 6th), we find the legs and thighs in a marked state of induration. The child's cry is still vigorous, but a fine crepitus may be heard in the lungs. This will be a fatal case; true sclerema is not cured, and death is generally the result of the extension to the external viscera of that rigidity which you notice in the external organs. In many cases of this malady, the incapacity of the lung to perform its functions is obvious, for the infant's head hangs over his chest, and a bloody saliva runs from his mouth. Most cases of sclerema, I might say all, are fatal; a difference of opinion on this point can only arise from errors of diagnosis, which may be accounted for in the following manner.—It is common to find children three or four months old, after diarrhœa or erysipelas, affected with limited œdema and hardness, which may be dispelled, but when, during the first month of life, without any functional lesion of the skin or any internal phlegmasia to explain the induration, a child becomes hard, he will surely die. M. Charcellay compares sclerema to the anasarca which sometimes follows scarlatina. He states that in both the urine is albuminous, and that both have their origin in a morbid condition of the kidneys. It is difficult to obtain the urine of so young an infant, but the research is an interesting one, and we will endeavour to ascertain its truth.

Tubercular Disease in Children.—Dr. Louis has stated that in childhood tubercles became frequent only between the ages of two and eight, and diminish in frequency from that period to puberty. This assertion could only have been made at a time when no special hospital existed for the treatment of diseases of new-born infants. During seven years, says Professor Trousseau, I have been attached to the care of infants at Necker's Hospital, and I distinctly assert that under two years, more infants die of tubercular consumption than of all the other causes of dissolution put together. It is a circumstance which must not be forgotten, that infants may be affected with tubercular disease, and yet present none of those external appearances which we generally refer to the diathesis. As an illustration of this statement, we may bring forward the case of the infant who died of meningitis yesterday. He was aged seven months, and was a remarkably fat, healthy, and lively-looking child. Both the parents were in the enjoyment of robust health; the child was suddenly seized with meningitis, and the malady remarkable besides by the manifestation of the characteristic red stain of the skin, the alternations of improvement which it presented, and the *removable* paralysis by which it was accompanied, was fatal in the space of five days. And I now present to you the lungs, spleen, liver, and intestines, studded with myriads of tubercles. On the surface of the cerebral envelopes, also, you may perceive numerous granulations strewed like a fine sand. It is not impossible that meningitis was in this case determined by the presence of these granulations; but I call upon you to remark that these granulations all occupy the convex surface of the cerebrum, and the anatomical changes resulting from the meningitis, are all, on the contrary, on the inferior aspect of the brain—a fact to be explained by the remark that whatever may have been

the determining cause of meningitis, it always presents the same symptoms, progress, and anatomical changes. The chief conclusion I wish to draw from this case is, to caution you, when you meet with meningitis in very young children although they may present none of the appearances of consumption, not to hasten to assert that the cerebral disorders have not originated in the deposition of tubercular matter. In a recent memoir, M. Rilliet states that meningitis often presents in children premonitory signs of very long duration occurring three and even four months before the outbreak of the malady. These prodromic symptoms would be crossness, somnolency, feverishness, and various functional signs of cerebral suffering. In our opinion, M. Rilliet's observations have borne too exclusively on cases of *tubercular* meningitis. Now, it is well-known that most of these are at the same time accompanied by visceral tuberculisation, and I am inclined to think that the crossness, erratic fever, &c., looked upon by M. Rilliet, as prognosticating meningitis, are only the symptomatic expression of a tubercular diathesis. Besides, in some cases of inflammation of the brain induced by the presence of tubercular granulations, we find sometimes only three or four granulations, forming so very small an organic lesion, that we cannot reasonably grant them the power of producing premonitory symptoms of any kind.

Rheumatic Paralysis of Nurses.—The disease I am about to describe is one which had never attracted my notice before 1841, and which I have never met with but in nurses. Do not attach any importance to the name I have given to it; I have used the designation only for want of a better. You may observe it in a woman at present lying in the wards. She was confined eight months ago, and continued in perfect health, nursing her child, for the next six months, when she was suddenly affected with the disease which has brought her to the hospital. Very often during the day, the patient is seized in one of her limbs with a sensation of numbness and formication, followed by spasmodic contraction and loss of power of the extremity; the symptoms last a few minutes, and reappear soon after in another limb, or in the tongue, throat, or eyes; in the latter case vision becomes indistinct, a ligature applied round a limb at once produces the spasmodic contractions. These are more frequent and severe in bed, and in the sitting posture. The patient's general health is good, but the frequent repetition of the symptoms has weakened her. The first time I met with this disease I was very much embarrassed. The patient had formerly suffered from rheumatism, and I fancied that her present symptoms might perhaps be attributed to the same unknown rheumatic element, so prone to migration I bled her, and she was cured. Since that time I have met with the same symptoms in eight or nine nurses, and in none had rheumatism preceded them, so that I still remain very much in the dark as to the intimate nature of the disease. However venesection proves in all cases sufficient to achieve a cure. The nurse at present in the wards had not passed, for the last two months, a single day without numerous attacks. We bled her yesterday morning, and none have occurred since. The blood is very fibrinous. At any rate, should you meet with similar case, Gentlemen, do not become alarmed about the state of the spinal chord, be convinced that the most serious (apparently) functional disorder of the nervous system may exist without any anatomical alteration of the nervous centres. I need only advert to nervous asthma, which is so frightful to behold, and yields so readily to the inhalation of stramonium, and to fits of hysteria, to impress strongly this point on your memory.

DAN. M'CARTHY, D.M.P.

Italy.

SUDDEN DEATH FROM SPONTANEOUS RUPTURE OF THE STOMACH.—Signor Morici, in the *Annali Universali di Medicina*, relates the case of a man, thirty years of age, who, after having suffered from intermittent fevers on several occasions, again experienced an attack, which was apparently cured in ten days. Five days afterwards he was suddenly seized with violent pain in the lumbar region. There was, however, no fever, no swelling, redness nor abnormal heat, nor hardness at the seat of the pain. The pain was aggravated on pressure, and the patient continually sat erect in bed, as it was impossible for him to lie on his back or side. Next day feverish symptoms made their appearance, accompanied with retraction of the right testicle, difficulty of making water, and a sensation of constriction in the sphincter of the anus. By the third day the fever had abated, and he was even able to take a little soup. In the evening he rose to go to the water closet, and in returning to his bed fell down dead. The thoracic viscera were found healthy, as were also the abdominal, with the exception of the stomach, which was ruptured on its anterior surface, almost in its very centre. The aperture was about three fingers' breadth in length, and had allowed the contents to escape among the abdominal viscera. Although the margins of the aperture preserved their natural texture, they were slightly hypertrophied and dotted with redness. The same dotted redness was remarked on the mucous membrane of the stomach a short distance around the rupture, but the membrane retained its natural texture, and had undergone no pathological changes. Signor Morici could not account for the production of the rupture, unless it were the straining at stool acting on a part of the stomach, weakened by circumscribed inflammatory action of the mucous membrane, as indicated after death by the dotted redness In this, as in all other recorded cases where the stomach has been found ruptured, the death was sudden, and was not attended with hemorrhage, or rupture of any arteries or veins of importance.

HERNIA OF THE STOMACH, TRANSVERSE ARCH OF THE COLON, AND GREAT OMENTUM INTO THE CHEST THROUGH AN OPENING IN THE DIAPHRAGM.—M. Battalia has published, in the *Giornale delle Scienze Mediche della Societa Medico-Chirurgica di Torino*, the particulars of a case in which there existed a hernia of the stomach, transverse arch of the colon, and great omentum into the chest through the diaphragm. The patient was a powerful man, twenty-nine years of age, and accustomed to drink. One night before M. Battalia saw him, he had drank exceedingly hard, and had afterwards given way to venereal excesses. The face was red and livid, thirst intense, breathing difficult, breath fetid, almost continual hiccough, violent nausea, vomiting of matters apparently stercoral, pulse frequent, irregular, and rather depressed, heat of the skin below the natural standard, obstinate constipation, and sensation of burning, with slight pain in the right iliac region. It was supposed to be a case of strangulated hernia, but no external evidence thereof could be discovered in the abdominal parietes; there was found, however, a cicatrix on the right side of the chest, which the patient said had been caused by a sabre wound received four years previously. It did not appear to have penetrated deeper than the integuments. Notwithstanding the most energetic treatment, the disease continued to make progress, and the patient died forty-eight hours after the commencement of the attack. Autopsy. The body presented a slight degree of tension of the epigastrium, and of the two hypochondria, the rest of the abdomen was flattened, and its parietes retracted towards the spinal column. On opening the abdomen, the small intestine and the peritoneum were found of a livid red colour, and in some places nearly gangrenous. There were old adhesions between the peritoneum and the viscera, and the liver was much enlarged. In the cavity of the peritoneum there was a small quantity of serosity of a dull-red colour. It was then ascertained that the stomach, great omentum, and a part of the transverse arch of the colon had passed into the right side of the chest, through an abnormal aperture in the diaphragm, and on carefully opening that cavity, the entire stomach was seen greatly distended, covered, and completely enveloped by the omentum, and the transverse portion of the colon lying between it and the diaphragm. The right lung occupied the upper and inner part of that cavity. The thoracic viscera were perfectly healthy, but there was a small quantity of blackish-red serosity in the pleural cavity, resembling that found in the peritoneum. The hernial viscera were greatly inflamed, and so strangulated by the aperture in the diaphragm, that they could not be returned into the peritoneal cavity without great effort, and the previous removal of the fluid with which they were distended. The opening in the diaphragm was of an oval shape, with rather hard and irregular edges, and was situated transversely a little above, and to the right of the œsophageal aperture; it extended as far as the tendinous centre, which was slightly torn. Its transverse diameter was about three inches and a half in length, the longitudinal diameter two inches and a half.

America.

BLACK AND WHITE TWINS.—Dr. Cunningham records in the *Philadelphia Medical Examiner*, the case of a negress, who was delivered of twins, one black and the other white. He says, a negro woman, aged about forty-five, after having given birth to thirteen children during her life, none of which were twins, was during the last spring safely delivered of two at one birth, one being black, and the other white. He saw them when they were a few weeks old, and the contrast in colour, hair, &c., was indeed striking, so much so, that four-fifths of those who examined them were of opinion that the negress was not the mother of both, but that some deception was being played; the mother persisted, and still declares them to be her own. Dr. Cunningham remarks on this singular fact that a black woman may give birth, at one time, to a black child and a mulatto, but the occurrence is extremely rare, but a case like that under notice he considers to be a phenomenon as inexplicable as it is interesting. The editor of the *Philadelphia Medical Examiner* suggests that the white child is either a mulatto or an albino. *⁎* With due deference to the judgment of those gentlemen, the second child may be white, and yet the negress be a mother of both the black and white offspring; and it is explicable by the supposition that she had sexual congress with a negro and a white man very soon after each other. A somewhat similar case occurred some years since in Jamaica, the female parent in that case being a white lady. She was delivered of twins, one black and the other white, and the explanation she gave was that soon after fecundating intercourse with her husband, a black man entered her room, and forced her to submit to his wishes, under pain of death.

NEW FORM OF DIRECTOR AND GORGET.—Dr. Mettauer, in the *Philadelphia Medical Examiner*, describes a peculiar director and gorget which he employs in the operation of lithotomy, and which he claims as his own invention. The director has a dove-tail groove, and the gorget a globular beak. He says, being early aware of the danger likely to arise from the accidental escape of the beak of the gorget—or knife, if that instrument be employed—from the groove of the director during its passage into the bladder, especially with inexperienced operators, the dove-tail groove of the director and globular beak of the gorget suggested themselves to him as improvements which would prevent such an accident; and abundant experience with the instruments thus modified, conclusively establishes their value and utility in guarding against it in the most effectual manner. Simply inspecting the instruments, if they are properly constructed, would satisfy even the most casual observer that it would be impossible for the gorget to pursue any other direction than that of the groove of the director. The beak should be well-formed with a globular finish, supported by a peduncle of sufficient strength to guard against its being broken by any moderate degree of violence from a twist, or irregular movement along the groove of the director. The director should be fully six inches long in the shank, with a handle some three or four, and of a size to fill the hand, so that it can be firmly grasped and securely held; and the two branches must form a very obtuse angle, with the groove on the side of the vertex or point of the angle. The director and gorget he employs are delicately formed, and in his opinion should always be so constructed. A probe-point should always form the termination of the director, so as to close that extremity of the groove. His mode of operating is simply to form the perineo-urethral incision, directed by a staff carried into the bladder; and then to introduce the straight director

just described, through the incision fairly into the bladder, along the groove of which the gorget glides to form the second, or the urethro-prostatic section As soon as the straight director enters the urethra beyond the proximal angle of the first incision, the staff should be carefully removed from the urethra

CÆSARIAN SECTION.—Dr M. M'Culloch, in the *British American Journal of Medical and Physical Science*, describes the case of a young female, who became the subject of extra-uterine pregnancy, followed by ascites. After the lapse of a few months, Dr. M'Culloch tapped her, and drew off thirty-six pints of fluid. The child could then, *for the first time*, be distinctly felt under the integuments, and the position of its body and limbs easily traced. The dropsy did not return, but the patient continued to suffer from fever and debility, until the middle of the succeeding year, the third of her pregnancy, when putrid matter, mixed with quantities of hair from the child's head, began to ooze from the navel. The skin was inflamed a few inches round an opening which would admit the point of the finger, and nature was, in this way, evidently making a most interesting effort to expel the child, and save the life of the mother; but she had become so feeble and emaciated, as scarcely to leave a chance of her surviving a few days. Dr. M'Culloch, therefore, under the circumstances, proposed the Cæsarian operation as her only hope. At the same time, her alarm was much increased by observing two worms escaping from the navel, and she, without hesitation, agreed to submit. Being then six miles distant from the nearest professional friend, he did not, under the circumstances, consider himself warranted in waiting for assistance; but had her at once placed on a table, and made an incision in the linea alba extending five or six inches downwards from the navel, and removed a putrid child of the ordinary size of birth. She did not lose an ounce of blood, and bore the operation with courage. No vestige of a placenta remained, and the child was found in a sac that had formed adhesions all round to the walls of the abdomen, and appeared to be the Fallopian tube enormously distended and thickened. It contained, besides the child, a quantity of very offensive matter. Nearly all the bones of the toes and fingers were found detached, and some of them adhering to the sides of the cavity were carefully removed; a small tent was then placed at the bottom of the incision to favour the escape of matter, and its edges were kept in contact with adhesive plaster, supported with a bandage. She afterwards continued to improve daily, although the thermometer, at the time of the operation and for several days after, was upwards of 90° in the shade. Her progress, notwithstanding, from a state of extreme prostration to perfect health was so rapid, that she was able, without inconvenience, to be taken six miles to church a month after the operation. She has since enjoyed excellent health, and, without regret, remains childless.

EXTENSIVE DISEASE OF THE STOMACH. — Dr. Paul narrates, in the Transactions of the College of Physicians of Philadelphia, the case of a gentleman, fifty-nine years of age, to whom he was called, in consequence of his suffering from weight and oppression at the stomach, with tenderness on pressure, headache, &c. The treatment employed relieved these symptoms for a time, and he became apparently convalescent. Some tenderness on pressure in the epigastric and abdominal regions continuing, twenty leeches were applied, but drew very little blood. Collapse set in some time afterwards, and he died the same evening. The examination post-mortem was made by Dr. Paul, Dr. C. Morris, and Dr. J. Neill. The external appearances of the body generally were natural; some lividity existed about the extremities. The abdomen was opened through the linea alba: the adipose tissue was one inch in thickness. On displaying the viscera in their natural position, there was exhibited a slight adhesion of the omentum majus to the parietes, at the epigastric region. Large patches of coagulated lymph were found upon the great omentum, which extended to the left hypochondriac region, completely covering the anterior face of the stomach, and a portion of the spleen. The superior face of the liver was also found coated by a lamina of coagulated lymph, which could be removed in masses The peritoneum of the parietes of the abdomen exhibited a venous injection, and the cavity contained a pint or more of serum. The stomach was removed, and found to be exceedingly heavy, weighing probably one pound and a half it contained a thick fluid of a light-brown colour Its walls were about half an inch in thickness—the increase being principally in the cellular and mucous coats The cellular coat, near the cardia, was filled with coagulated lymph, which became less firm near the middle; at the pylorus, the cellular coat was distended to the same thickness with serum. The mucous coat exhibited great changes in structure and appearance—being much thickened and very firm; its hue was florid—the colour being deeper at the greater curvature. Its surface presented a very rough, granular formation, each projection being about the size of a grain of coffee, or larger. These were dense and unyielding to the touch, and more vascular than the surrounding tissue; they were more numerous at the greater curvature. The liver presented no unusual appearance in its glandular structure. A section of the upper part of the jejunum, and a section of the ileum, were examined; but presented no appearance of disease in any of their coats, except the injected peritoneum. The examination was interesting in many respects. It proved that, with such altered structures, the case was beyond the reach of medicine. It presented traces of great inflammation, with little accompanying pain. It presented abnormal structure, which must have taken time to form during, apparently, the enjoyment of good health. It shows that extensive disorganisations may take place in some tissues, without the occurrence of any symptoms by which their existence is revealed either the patient or his physician.

MALPOSITION OF THE KIDNEY.—Dr Diver, the *Philadelphia Medical Examiner*, describes malposition of one of the kidneys found in a subject brought for dissection. The kidney, which should have been found in the left lumbar region, was situated in the pelvis, immediately below the promontory of the sacrum. It was much smaller than the kidney of the right side, and derived its artery from the common iliac of the right side, about half an inch below the bifurcation. A deep sulcus was formed upon its surface for the passage of the renal artery. The convexity looked upwards, and the pelvis was much distended, owing perhaps to the gravitation of the urine. The distribution of the renal artery was very remarkable in this case, arising as it did from the common iliac of the right side Another peculiarity in the distribution of the branches of the abdominal aorta was, an arterial branch corresponding nearly in its origin to the inferior mesenteric, but which took a course along the lumbar vertebra without giving off any branches until it dipped down behind the bladder.

HYDRIODATE OF POTASH IN TYPHOID FEVER.—Dr. Voigt, in the *Philadelphia Medical Examiner*, describes a case of typhoid fever in which he exhibited the hydriodate of potash with marked benefit.

England.

[The following are the only articles of interest to the profession in the last No. of the *Lancet*.]

DISEASE OF THE HEART.—Mr. Hodson gives the post-mortem appearances observed in the body of a young man, of exceedingly intemperate habits, who came under his care, while in a sinking state. The principal symptoms were jaundice, diarrhœa, emaciation, and urgent dyspnœa. The liver was found to be in the first stage of cirrhosis; the stomach tolerably healthy, the lungs particularly so; the pericardium contained about seven ounces of serum. The right (?) side of the heart presented concentric hypertrophy of the left (?) ventricle with "vegetation" disease of the semilunar valves. Contained in the chamber of this ventricle, there were from fifty to sixty globular membranous sacs, filled with a puriform fluid, and varying in size from a pea to a small nut. They were slightly adherent to the walls of the ventricle by a small portion of their surfaces between the columnæ carneæ, the smaller ones being thus almost hidden, and the larger projecting into the chamber.

THE METHOD TO BE OBSERVED IN CONDUCTING POST-MORTEM EXAMINATIONS FOR LEGAL PURPOSES.—Dr. Letheby recommends the following plan to be adopted in conducting post-mortem examinations for legal purposes:—1. Record the name, age, and sex of the deceased. 2. Note the day and time at which the examination is made, and set down the period which has intervened since death. 3. Direct attention, as early as possible, to surrounding circumstances, as to whether there is any weapon or trace of blood near, any cup or bottle likely to have contained a poison, or any evidence whatever in the positon of things about the body to indicate a struggle or the cause of death. 4. Observe the position of the body Is it in bed or on the ground; and how does it lie?—or is it suspended? and so on. 5. Is the body naked?—or are the clothes on? and are these disturbed or torn? 6. Notice the position of the limbs. Are they or the fingers bent, as if convulsions had preceded death? Open the hands, and search for anything which may have been torn from an opponent during the death struggle. 7. Observe the appearance of the countenance, as regards its colour and expression. Are the eyes open or prominent? What is the state of the conjunctiva and pupil? Is the mouth open, or is there any foam about it? Does the tongue protrude, or is it bitten? Smell the mouth, and notice the colour of the gums Connected with this part of the inquiry it may be said that the countenance will often give an important indication of the cause of death, and of some of the circumstances which immediately preceded it. Thus, as regards its colour, it is mostly livid after apoplexy and death from hanging or strangulation, and pale from hydrocyanic acid, the mineral acids, and the alkalies, as well as from most of the vegetable poisons, from blows upon the epigastrium, or injury some vital organ On the other hand, it may be either pale or red after poisoning by carbonic acid, alcohol, or opium, and some other poisons. The expression of the face, too, is generally convulsive when there has been much struggle immediately before death, as during hanging, drowning, or poisoning by prussic acid, strychnia, and nux vomica; and it is often convulsed in cases of death accompanied by great hemorrhage. On the contrary, here is more frequently a calmness in the expression after death from apoplexy, opium, carbonic acid, &c., while the features are pinched, and there is an anxiety in the look after the action of the metallic and most vegetable poisons. The eye also is generally open, prominent, and glazed, after the effects of hydrocyanic acid, and prominent and injected after death from apoplexy and strangulation. Some authors, moreover, have described a suffused or even ecchymosed condition of the conjunctiva after death from arsenic. The foam about the mouth is very characteristic of prussic acid, while the bitten tongue would indicate a great struggle or convulsive action immediately before death. The gums put on a blue appearance after poisoning by lead, and the red or spongy gum, or even an ulcerated condition of the mouth, is often indicative of the action of mercury. It must be remembered, however, that the same appearances, together with extreme salivation, have been produced by other substances, as iodide of potassium, colchicum, fox-glove, croton oil, and some other metallic and vegetable substances. 8. Proceed to remove all clothes from the body, and observe if there has been any evacuation just before death, either from the stomach, rectum, or bladder, or if there has been an emission of seminal fluid. All of these appearances indicate convulsive action, and the latter, which is the common accompanyment of death from hanging, points to an irritation of the upper part of the spinal cord, and may serve to establish the fact of suspension before death, supposing that an opposite question were to arise. 9. Note the appearance of the body, whether deceased was fat or thin. Observe the colour of the skin, whether it is livid in any part, or if it presents any marks of violence, and if putrefaction has commenced. The colour of the skin is exceedingly pale when there has been much hemorrhage before death, or after starvation, &c., and it acquires a yellow tint after poisoning by lead and copper, it is often ecchymosed or covered with purple petechiæ after arsenic, and some wasting diseases. The dependent parts are generally very livid soon after death by hydrocyanic and carbonic acids and when

there is any mark of violence, this should be accurately described, considering by what means it was likely to have been occasioned, whether it could have happened by accident, or by the hand of deceased, or by that of another person In examining wounds about the throat, it is of great importance to notice on which side of the neck the wound is deepest, for this may indicate where the cut was commenced, and whether it was made from right to left, or from left to right dissect them also to learn what parts have been involved in the division. If there is any mark of a cord around the neck observe where the knot pressed, or where the cord was crossed; for one person would, in all probability, strangle another by crossing it behind, while in a case of self-murder it would most likely be crossed in front. Lastly, it is of great consequence to know whether the wounds or bruises were produced before or after death, and although this cannot always be confidently stated, yet there are circumstances which will often furnish very important indications,—as the absence or presence of coagula in the wound, or of ecchymoses around it, or of infiltration of blood, fibrin, or serum, into the surrounding tissue; Dr. Letheby remarks that most post-mortem wounds soon dry and discolour upon the edges, acquiring a brownish parchment-like appearance. With respect to the evidence furnished by putrefaction, most poisoned and plethoric bodies putrefy quickly, and especially those of persons who have died soon after a full meal, while, in the reverse cases, and after poisoning by arsenic, there is generally a delay in this process. 11 Can any opinion be formed as to the time which has elapsed since death took place? This is often a very important question, and may involve an answer having a certain day, or even hour, for its limit. The post-mortem signs are not by any means so constant in their occurrence, or so conclusive in their import, as to warrant us in making on all occasions such a positive reply. The evidence upon the subject may be collected somewhat after the following manner —(a.) Is there any warmth in the body? Dr Letheby found that adults cooled pretty constantly after this manner —the extremities lost their heat very rapidly, sinking to the temperature of the room in less than three, while the surface of the trunk has felt warm, even up to the twenty-fourth hour, and at this time, a thermometer, placed either in the axilla or rectum, has generally stood at somewhere about 70° Fahrenheit In fact, these parts have hardly ever lost the whole of their heat until after the lapse of thirty-six, or sometimes forty-eight hours. There are many circumstances, however, which may modify the order of things, as, for instance, the body would cool faster if it were exposed to a current of cold air, or immersed in cold water, children and very thin subjects cool sooner than adults, or corpulent ones. Again, when the body has remained in bed, or been well clothed, and surrounded by bad conductors, the temperature is retained for a somewhat longer time (b) Has the rigor mortis set in? It most commonly happens that the limbs begin to stiffen in about two or three hours after death, and the rigor is generally firm and complete after the lapse of seven or eight hours To this, however, there are occasional exceptions, as, for example, it is nearly always accelerated when the fatal event has been sudden, and when, immediately before death, there has been violent convulsive action, or a prolonged muscular exertion. In such cases the living spasm appears to pass at once into the dead rigor. Look, for instance, at the suicide, who is often found with the weapon firm in his grasp; and so with the murdered and the drowned, who frequently retain their hold of objects which had been clutched during the death struggle. Cases, on the contrary, now and then occur, in which the rigor mortis appears to have been delayed for a very considerable period Such, however, is rarely the sequence of sudden death, but is indicative of some inflammatory action immediately before death. (c) What is the condition of the cornea? In general the cornea becomes slightly clouded after the lapse of nine or ten hours. In about sixteen this condition is still more evident; it then gets somewhat lax, is easily indented on pressure, and when this is made upon the side of the eyeball, the cornea becomes still more opaque. In about twenty-four hours it commonly acquires perceptibly greater laxity, and in forty-eight it may become quite flat, and so opaque, that the pupil can hardly be defined through it. (d) Has putrefaction commenced? This is rather an inconstant event, and is liable to be interfered with by many modifying circumstances, such as the temperature of the room, the time of the year, the condition of the body, the cause of death, and whether it occurred soon after a meal or not, and so on. In about eight or ten hours after death the surface of the body, especially over the chest, and on the inside of the arms and thighs, puts on a marbled appearance, due to a turgescence of the superficial veins. In about sixteen hours, the dependent parts become livid or reddish purple, and after the lapse of twenty four hours this lividity is generally very marked, and the marbling on the chest and arms begins to acquire a purplish tint About the second day it assumes a brownish hue, and at this time the abdomen and groin show more evident marks of the putrefactive process, by acquiring a green colour. From this period it advances with more or less rapidity, according to attendant circumstances. In five or six days, the entire surface is ordinarily very green, and the venous marbling still strongly marked About this time, in warm weather, the epidermis begins to loosen, and the fluids acquire great liquidity, and gravitate to the dependent parts, through which they readily escape beyond this, the track of decomposition can scarcely be followed with any certainty. 12. What are the evidences which show that death has really taken place? (a) An absence of cardiac pulsation, and of the respiratory movements. (b) A loss of sensibility in the excito-motory system, as when the eyelids cease to wink on being touched, or the limbs and muscles to move on being pinched or pricked; one of the most powerful agents as a test of this function is galvanism. The muscles lose their faculty of contracting under its influence in about three hours after death. (e) The appearance of the rigor mortis, which generally sets in after about two or three hours (f) The loss of temperature in the body. (g) The opacity or cloudiness of the cornea. (h) The lividity of the dependent parts, and the mottling on the arms and chest. (i) The setting in of putrefaction. Of all these signs of death, the second merits the greatest consideration, because of the certainty of its import and of the early period at which it generally manifests itself.

13 Examine the head, and note if there is any bruise on the scalp, does the latter bleed freely as if its vessels had been congested? 14. Are the membranes of the brain natural, and is there any fluid upon or beneath the dura mater; note its quality and quantity and when there is any blood, observe if it is coagulated or not. Are the vessels on the surface of the brain gorged or not; and is the blood liquid or dark? All the considerations which arise from these inquiries will be well enough understood, but it is to be remembered that apoplexy, and, according to Dr. Conolly, epilepsy complicated with mania, will nearly always produce an extreme congestion of the vessels of the brain, and even in some instances effusion of blood between the dura mater and arachnoid. 15. Remove the brain, and examine it by making a series of thin horizontal slices, until it reaches quite to the base; observe if there has been any softening, or if there are any bloody points indicative of congestion, if any blood or serum has been effused into its substance, or into the ventricles, and what is the condition of the choroid plexus If the brain has not been examined in this careful manner, difficulties may arise in after stages of the inquiry, for no person can pretend to say whether it was diseased or not. 16. Examine the calvarium and the base of the skull for any fracture.

POISONING BY VERDIGRIS.—Dr. Moore describes an endemic inflammation of the stomach and bowels occurring among the Coolies on board ship from the carelessness of the cooks in not cleansing the copper vessels used for the food, the consequence being that poisonous doses of the salts of copper were mixed with the rice, &c, and numerous cases of enteric and gastric inflammation resulted, one of which terminated fatally. Wooden dishes and platters were afterwards employed The appearances after death in the fatal case were, on the internal surface of the stomach, from the cardiac to the pyloric extremity, and for a short distance on the internal surface of the œsophagus, near its termination in the stomach, extensive and deep-seated inflammation of the mucous membrane and subjacent tissues; the shades of red varied in different parts from a bright vermillion, or bright scarlet, to a deep red or violet colour. The patches of dark red approaching to a brownish colour were comparatively small and circumscribed, situated in general beneath the mucous membrane of the under surface of the stomach. The mucous membrane corresponding to these patches was soft, tumid, pulpy, but not excoriated, and free from the appearance of having sloughed. At the pylorus, the membrane was intensely inflamed, glistening, tumid, from a quantity of serous fluid exuded beneath the sub-mucous cellular tissue. In the duodenum, there existed the pathological appearances of a high state of inflammatory action: throughout the small intestines also there were decided traces of inflammatory action in the mucous membrane, although scattered irregularly over the surface. The mucous membrane of the large intestine presented, in like manner, an appearance of vascularity; in the rectum also, the inflammatory action had commenced, but was limited in extent. Within the peritoneal sac, somewhat more than eight ounces of saffron-coloured fluid were found the peritoneal coat of the small intestines—the jejunum and ileum, was numerously studded with minute circular dots, or specks, of a bright scarlet-red colour. On the upper surface of the arch of the colon, in its ascending and descending divisions, these inflammatory spots were extensively, but less numerously, scattered. Between the peritoneal and muscular coats of the stomach, an irregularly-shaped patch of effused blood was noticed, and on the lateral and inferior surfaces of the same viscus, vascularity of the peritoneal coat, and sub-peritoneal exudations of blood and lymph, were traced to a short distance. The folds of the intestine were not agglutinated together by lymph, nor were there any traces of it in the peritoneal sac.

Scotland.

DISEASE OF THE HEART.—In the *Edinburgh Medical and Surgical Journal*, Mr. Wells narrates, under the head of diseases of the organs of circulation, two cases of disease of the heart. The first is that of a marine, who presented all the symptoms of obstructed pulmonary circulation—blueness of surface, œdema, and turbulent action of the heart, with loud double bruit. He was relieved by bleeding, but the symptoms were afterwards aggravated, and the case terminated fatally. At the post-mortem examination both lungs were found extensively congested, and about a pint of serum in the left pleural cavity Four ounces of fluid were contained in the pericardium. The heart was much enlarged by hypertrophy and dilatation of all its cavities. The pulmonary and tricuspid valves were healthy. The aortic orifice was in a state of permanent patency from disease of its valves, which were covered by vegetations, and one was perforated, leaving a small opening The mitral valves were also thickened, and a small tumour the size of a pea had formed in one of their divisions. All the cavities were much distended by blood and fibrinous coagula. The liver was extremely congested. There were no other signs of abdominal disease. In the second case the principal symptoms were dyspnœa and palpitation, the pulse at the wrist and the brachial and axillary arteries of the left side being always almost imperceptible, while that on the right side was of the natural strength. A rough bruit de soufflet was often heard over the arch of the aorta, but was by no means constantly present. Death occurred suddenly. The lungs were found to be excessively gorged with blood. The heart appeared much larger than natural, but this was more from distension than increase of structure The auricles, coronary veins, and superior cava were enormously distended, and a considerable quantity of fibrine had formed in the ventricles. The aortic valves were hardened, thickened, and contracted; contracting also to some extent the aortic orifice. The ascending aorta, its arch, and a few inches of its descending portion were studded with atheromatous deposit

between the internal and middle coats, and the internal coat in some few spots had ulcerated. This deposit was most considerable about the origin of the left subclavian artery, and the mouth of that vessel was so much contracted as scarcely to admit the end of a small blow-pipe.

Pelvic Abscess from Ulceration of the Urethra.—Mr. Wells in the same paper, "a Report of Cases treated at the Royal Naval Hospital, Malta," describes the post-mortem appearances in two fatal cases, in which the strictured urethra had ulcerated. In the first case, one of previous stricture, the injury appeared to have been induced by a fall in which the perineum received the principal shock. The man died from the effects of extensive sloughing. On examination, the abdominal organs were found to be in a perfectly healthy state, without any signs of peritonitis. The cellular tissue of the pelvis, anteriorly below the reflection of the peritoneum, formed an immense sloughing abscess, which passed downwards on the right side, along the course of the cord to the perineum and recto-ischiatic spaces. On a metallic bougie being introduced by the urethra, it passed into this abscess through an ulcerated opening in the urethra, just where that canal passes through the triangular ligament. The urethra in this situation had evidently been the seat of chronic disease, its coats being hard and thickened. The edges of the opening were rounded off. The urethra at its external orifice was so small as scarcely to admit the smallest sized bougie; but after the first inch its calibre was natural throughout. The bladder was perfectly healthy. In the second case the disease was of a more chronic character, and the patient died, worn out by profuse suppuration. The genito-urinary organs were the sole seat of disease. A small stricture existed about one inch from the meatus, and from this to the membranous portion the urethra appeared healthy. At the latter situation the mucous membrane was black and ulcerated, and opened into a large abscess, which filled the space between the rectum and the bladder, and recto-ischiatic spaces. It was distinctly encysted, and its walls were black and fetid. The prostate was healthy, the bladder much contracted, and both ureters much dilated. The whole of the mucous membrane, from the membranous portion of the urethra, through both ureters into the pelves of both kidneys, was in a black sloughing state, and presented numerous points of ulceration. The kidneys were in an advanced stage of granular degeneration.

Gangrenous Inflammation of the Femoral Muscles.—Mr Wells, in the same report, describes a case, of which he says it was not all clear from the symptoms whether disease of bone, cartilages, or periosteum, erysipelas, or phlebitis, had been the primary disease. The patient was a marine, thirty-five years of age, who was admitted into the hospital with supposed rheumatism of the right knee. Matter formed beneath the deep fascia of the thigh; the femoral vein became knotty and swollen, and emphysema became very distinct in the inner part of the thigh, and afterwards extended above Poupart's ligament. Five openings were made, and excessive fetid discharge continued, notwithstanding the use of wine, porter, quinine, and generous diet. The man died exhausted. On inspection, fibrinous coagula were found in the right cavities of the heart, extending along the venous trunks. The vena cava ascendens was considerably distended by air, not fetid. The internal iliac veins on each side were healthy; the left external contained some partially adherent clots, and the right was completely occluded by fibrinous clots which were slightly adherent to the reddened internal membrane. The femoral and popliteal veins on this side were in a similar condition. Scarcely a trace of any of the muscles of the thigh remained; the bone, covered by shreds of gangrenous cellular and fibrous tissues, running through the centre of an enormous abscess with sloughing walls. At the popliteal space the cavity of the knee-joint communicated with the abscess, and was filled with the fetid debris of the tissues of the thigh; the cartilages of the articulating surfaces of the femur, patella, and tibia, being in a great measure removed. Extensive superficial necrosis of the femur had taken place. No purulent matter was found in any of the veins, nor any purulent deposit in any of the organs. The knee-joint was the only one which had been the seat of disease.

Cellulitis Venenata.—In the same report Mr. Wells details at some length the particulars of a case of cellulitis venenata caused by a dissection wound in opening the body of a patient dead from phthisis. The disease terminated fatally five days after admission into the hospital. The treatment adopted at first was antiphlogistic, and afterwards stimulant. On examining the body after death, the heart was found very much distended by fibrinous coagula, which adhered very firmly to the walls of its cavities. There was also some hypertrophy of the left ventricle, old adhesions of both pleuræ superiorly and anteriorly, and extensive infiltration of both lungs with bloody serum. The cellular tissue of the right hand, forearm, and part of the upper arm, was thickened and infiltrated with a dark-coloured serous fluid. From the dorsum of the carpal phalanx of the index finger, the wounded one, a vein filled with purulent matter passed to the superficial radial vein, and on to the median cephalic. As this vein proceeded up to the forearm, coagulable lymph lined its internal coat in distinct layers, which became thicker before the junction with the medium basilic, and there so completely plugged the vein, that the entrance of purulent matter into the deeper veins was prevented. The blood for some distance along the brachial veins was clotted, and their internal coats reddened. Nothing was observed in the course of the examination which could lead to the inference that purulent matter had entered the general circulation.

Purpura.—In the same report Mr. Wells records a case of purpura, which terminated fatally, stupor, stertor, and other symptoms of cerebral effusion, occurring shortly before death. The post-mortem examination showed the vessels on the superior surface of the brain turgid with dark fluid blood. The substance of the cerebrum and cerebellum was healthy, with the exception of the parts around the right lateral ventricle. This cavity was distended by about two ounces of blood, partly fluid, partly dark adherent coagula. The greatest quantity was in the posterior horn of the ventricle, and the surrounding cerebral tissue was softened and broken down. A considerable quantity of blood had made its way through the softened cerebral tissue, and diffused itself beneath the arachnoid, around the convolutions in the cells of the pia mater. The effusion had apparently proceeded from the choroid plexus, which was much enlarged, pale, and very fragile. The left ventricle contained only bloody serum, but the blood itself had extended into the fourth ventricle. The lungs, pericardium, heart, and the external surface of the liver, were studded with purple spots. There was slight dark-coloured injection of the small intestines, principally in the duodenum, and the mucous membrane of the stomach was injected throughout in the punctated form. The spleen and pancreas, and also the kidneys and bladder, were healthy.

ORIGINAL LECTURES.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

By G. J. GUTHRIE, F.R.S., &c.

INTRODUCTORY LECTURE.

Gentlemen,—I have long promised to write one or two more books in connection with the many different points in surgery which I have already noticed. My record of the "Surgery of the Peninsular War," for instance, is incomplete. That part which relates to the injuries of the chest, the abdomen, and the pelvis, is scarcely known except to those who formerly attended my lectures; and the consequence is, that many students are unacquainted with the improvements introduced into the treatment of them during that war, although thirty years have since passed away. Many of the gentlemen who come before me at the Court of Examiners of the College of Surgeons are exceedingly ill-informed on these subjects, although they have fairly studied many others. Some do not even know when a man is stabbed on the right side of the chest, whether he should lie on that side, or on the other, or on his back, and even if they should answer correctly, it is by no means uncommon for them not to be able to give a reason for the selection. If they seldom know this, the very first step to be taken in the treatment of these injuries, it may readily be inferred how little likely it is, that they should know other and succeeding parts more accurately. I can safely say that scarcely one student I have examined, in the eighteen years I have been an examiner, has been able to tell me the proper treatment to be pursued with regard to an incised wound in the chest, into which the lung had protruded, even if he were able to describe what ought to be done when it did not. When I was first elected into the Council of the College of Surgeons, an honour conferred upon me at an earlier period than had ever befallen any other person, not on account of any merits of my own, but from the reflection of those of others which I had been the means of placing on record, the elderly gentlemen were, it is said, but little acquainted with these injuries. Sir Peter insisted that every man should be bled, because he had the misfortune to be stabbed—Sir Roger, that he should be thoroughly physicked, in order to allow of a free descent of his diaphragm—and Sir Richard was for keeping his wound open, that the secretions might readily flow out, until the proper time for duly closing it should arrive. If the bleedare, the purgare, and the clysterisare system did not suffice, it was admitted that there was nothing better to be done than to rebleedare, repurgare, and reclysterisare, as Moliere and his associates had recommended to be done before. The grinders of the present day instruct their aspirants to close such wounds without delay, to eschew calomel and jalap as incompatible with the absolute rest such cases require, even if the diaphragm should not descend with perfect freedom, and not to bleed in expectancy.

Wounds of the abdomen were not in more fortunate consideration. The elder surgeons brought the edges of a cut in the wall of the belly of three inches in length, into some sort of apposition by two stitches of several good thick threads, introduced at equal distances through the muscles down to the peritoneum, but woe to the man who thought of touching this inner lining. Having been thus stitched up, which was of itself enough to aid him out of this world—if the accident itself had not been sufficient—he was then to be thoroughly well physicked, and bled ad libitum.

An accomplished grinder now disapproves as much of a stitch in a muscle as the surgeons of old did of one in the peritoneum, and as he crams in turn his expecting students with the peculiar doctrines of Mr. A. or B., he teaches them to sew up the skins, and the skins only of their patients, exactly as their mothers would do a hole in their best pocket-handkerchiefs. He inveighs against salts and senna, and protests that they do not accord with that state of quiescence which can alone save the patient.

Surgery has followed in the wake of other things, and has yielded to the dictates of experience, founded on observation. It has been, however, somewhat slower in its progress than other matters of science which are commonly valued at a higher rate, than the art of saving life.

Gentlemen who have accidentally seen one or two cases of wounds of the chest, have sometimes thought themselves at liberty to lay down what they call principles to be followed in all cases of the kind; and it has been a matter of surprise to many to find their precepts doubted by those who have had greater opportunities for observation than themselves. Few, like my late learned friend, the professor of military surgery in Edinburgh, have the candour to acknowledge the erroneous nature of the opinions they had been taught, or the honesty to avow that they were altered. I think it was a Whig Government that created, very many years ago, the office of professor of military surgery in the University of Edinburgh, to reward the services of a zealous medical supporter, resting their defence of the new appointment upon the grounds

that the individual in question, being a civilian who had never seen a shot fired, nor any sort of military service, was at least open to conviction and improvement—that he was a sort of tabula rasa, as far as experience was concerned. The professor was really a learned and a most honourable man, and an able surgeon, and taught what he did know in a manner which gained him universal approbation. Nevertheless, there were some things he did not profess to know too well; and when the battle of Waterloo was fought, he was glad to avail himself of such an opportunity of acquiring information, and hastened to Brussels, with a full recollection in his mind of Mr. J. Bell's work on Wounds of the Chest, which he had particularly studied and admired. One part of this treatise is elaborately written; the description of the inflation of the whole of the cellular membrane of the body which ensues after a gun-shot wound of the chest, is so truly graphic, so beautifully described, that it is even now frequently referred to as an admirable specimen of surgical writing. An unfortunate man, lying with a musket-ball in his chest, and gradually swelling up, until he parodies in appearance the ambitious frog in the fable, naturally attracted the sympathy, and lived in the recollection of every one. When the learned professor reached Brussels, his first question to me was, "Did you see many of the cases of emphysema so well described by Mr. John Bell in his admirable book on wounds, when you were in the Peninsula? How many are there here? You must have heard of every good case—do show me some of them." I replied, with all becoming gravity, that the last case I had seen of general emphysema was at Tarbes, after the skirmish which took place in front of that town. A poor creature was brought into the square before my door, one morning, apparently dead. He was carried by three men, with long white sticks in their hands, followed by a fourth with a pair of bellows. The three first had scarcely put him down, when to my astonishment they began to strike him smartly with the sticks, and the fourth, before I could get down to interfere in his behalf, had cut a hole in his skin, near the bottom of his back, into which he introduced the muzzle of the bellows, and in an incredibly short space of time had blown him up to thrice his natural size. The incredulity shown by the worthy doctor at this relation of my case rendered it necessary for me to explain that the patient was a calf, and that the four butcher boys had in three minutes fairly outdone John Bell. The professor and the friends who accompanied him declared I was laughing at them, and could scarcely credit my assurance that I had never seen such cases as the late Mr. J. Bell had described, and that they would nowhere find them, except in Mr. John Bell's book. The doctor was, however, easily satisfied they were not to be found in Brussels. He soon understood that a musket-ball makes too large a hole to admit of such a thing taking place, although it possibly may occur from a stab, or small hole, which may not prevent the closing of the external opening, whilst the inner wound into the cavity of the chest, communicating with the lung, remains pervious. The learned professor smiled on hearing this explanation, and said, "I am afraid I have much to learn, and more to unteach"—an acknowledgment which did him honour. He remained at Brussels long enough to make an epitome of all the interesting cases he saw, which he published on his return, and by it gained great credit. The result to himself was not bad, and there is certainly no ill-will in the story, although perhaps there may be some little satire in telling it. The Tories were in office on his return, and were determined not to be outdone by the Whigs, in rewarding a meritorious servant. They thought that as their political opponents had made him a professor when he knew but little of the subject he was to teach, something ought to be done for him when he had well qualified himself for the office. They therefore made him a staff-surgeon, the full pay of which he enjoyed for a long time, and the half pay until his decease. You may learn from this anecdote, that a good surgeon and a zealous politician are sometimes not incompatible nor disadvantageous qualifications.

There are few occupations more troublesome than printing or publishing books when the stimulus of necessity is wanting, and when the subject precludes all hope of pecuniary profit. My publishers for instance, persuade me to pay for the paper and printing of a book, as a first expense, and then to allow them 10 per cent. commission for taking care of it, which, together with 30 per cent. allowance to the retailing booksellers, with the additional advantage of receiving thirteen as twelve, makes 50 per cent., leaving 50 to pay for paper, printing, and advertisements. Direct profit is not therefore to be thought of from a book on wounds, &c.; the indirect profit, it is said, might be incalculable, if people were not so seldom shot or run through the body as to indispose them to buy books which treat of such matters. I willingly pay for a book that people will buy on more common complaints, or accidents in which they may be immediately interested; but I have been careless of doing so for those which are not likely to pay either directly or indirectly. I now content myself by allowing my opinions to appear before the public through the medium of such of the weekly medical journals as may please to publish them.

The treatment of wounded arteries is not better understood by students in general. They can all answer that a ligature ought to be placed above and below the wound in the artery, or on both of its ends when divided; but try them on the means to be adopted in a punctured wound of the axillary artery, or of the femoral, or in a case of wound of the calf of the leg, in which it is doubtful whether one or both of the arteries are injured, and they are lost. If they fly for assistance to Mr. Hunter's theory for the cure of diseased arteries, they will find a method of proceeding which is never successful when put in practice for a wounded artery, or at least so seldom successful as to form only an exception to the general principle already mentioned, and which can never be departed from without imminent danger to the limb, if not to the life of the patient. It is not less extraordinary than true that different principles, as they are called, are taught in different schools of surgery in London, and my examinations on these points frequently become courses of instruction, instead of inquiry, and I am in consequence obliged to exercise a leniency, when about to pronounce sentence of approval or rejection, which often materially interferes with my sense of public duty.

Anatomy has its little differences as well as surgery. The learned professors of school No. 1 teach that a femoral hernia descends into the sheath of the femoral vessels. The no less learned professors of school No. 2 declare that it is on the contrary, projected against the part only which is going to form the sheath, and that it descends in a separate tunic of its own, by the side of, but distinct altogether from, the sheath of the vessels. With these gentlemen I concur in opinion. The very able professors of school No. 3 teach that this same femoral hernia comes out in the thigh at the saphenous opening. The equally able professors of school No. 4 declare that it has little or nothing to do with the saphenous opening; to which opinion I assent. The most perfect of grinders cannot get over this. He is obliged to beat two opposite opinions into the heads of his *élèves* in the morning, and two more in the afternoon, that he may be able more conveniently to cram them again all round with the whole four in the evening. How can this be settled? One of the medical bills lately introduced into Parliament, but which did not long remain there, provided for the establishment of a Council of Health, so called on account of its having nothing to do with the health of any one person whatever, but which name was possibly selected because no one could suspect that, to a body constituted under so unassuming—nay, benignant—a title, powers were to be granted of a more arbitrary and oppressive nature, more subversive of the rights and best interests of individuals than any which have been conveyed by any other act of Parliament. One of the clauses of this bill empowered this council, or medical inquisition, as it ought to have been called, to ascertain whether the examiners of the different colleges did their duty to the satisfaction of the council. If they had not done so, men of only ordinary minds might perhaps have thought it right to give authority to the council to admonish the examiners. The authors of this bill thought otherwise. They empowered the council to punish the students, to refuse them (although declared competent by the examiners) their authority to practice, without which they could not legally do so; and thus, in fact, to destitute them, to turn them out to starve, until the examiners should acknowledge their errors, and amend their ways. If any of these bills should re-appear, I will do my endeavours that a clause shall be inserted by which these anatomical differences may be quickly adjusted, and the provision to be made for this might be, "that until the professors can agree upon anatomical facts which admit of clear and easy demonstration, the students shall be annually cobbed, at the end of each session."—one clause being a *pendant* to the other.

The war in the Peninsula terminating, it may be said, by the battle of Waterloo in Belgium, added much to the character of the British army, and to the military renown of the nation, whilst the miseries caused by, and attendant upon it, have led to the improvement of the art and science of surgery in a degree which neither could or would have been effected without them. My late friend, Sir Astley Cooper, took pleasure in declaring that the practice of that war had given to surgery its greatest impulse in the present century, and the admission showed an honesty and nobleness of disposition it would well have become others to have imitated.

Engaged from the first battle on the heights of Roliça, to the last of Toulouse, and subsequently at Waterloo, generally in the field, or in charge of a principal part of the wounded afterwards, there was no one who, from his labours or his opportunities, had a better right to take upon himself the humble office of recorder and historian of the surgery of that war. When I undertook this duty, thirty-one years ago, I laboured under one great defect, to say the least, which time has however removed. I was not twenty-nine years of age. I had wrung from the authorities at home the inspectorial rank I held by dint of hard work alone, and I was afraid of giving offence to those I had distanced in the course by assuming anything to myself. Nothing, therefore, could be more humble and unassuming than the expression of my views in the first and second editions of my book on Gun-shot Wounds, and the Operations of Amputation. They were followed by so much change in the opinions of the profession on the points to which they adverted, that whilst few objected, and none refuted, some were not ashamed to appropriate an improvement or two as their own, and to sneer at what they were not equal to disprove, or to overturn. In 1827 I published the third or greatly enlarged edition of my treatise on Gun-shot Wounds, on Inflammation, on Erysipelas and Mortification, on Injuries of Nerves, and on Wounds of the Extremities requiring the great operations of amputation of the hip-joint, shoulder-joint, &c., with a preface, in which I *then* felt it right towards the medical officers of the army to claim for them the improvements they had introduced. It is as follows:—

When I printed the first edition of this work, in 1815, I stated, that it contained "many opinions in opposition to those received in common by the profession, and even now taught." I also said, that in publishing them I was desirous of making known "What had been the practice of the surgeons of the British army during the Peninsular war, and to preserve for them the credit of the improvements which they alone have introduced into the science and art of surgery, and particularly in the operative part, in which they have been eminently successful." In referring to my professional brethren that credit which was their due, I by no means wished to exonerate myself from any blame that might be attached to the practice recommended, for I was aware that some of these opinions were not common to the whole, and for those in particular, as well as for every one of them, I held myself responsible. I was contented to allow them to find their way as unobtrusively as possible into the world, satisfied they would stand the test of investigation, and be ultimately adopted as principles. In this I was not mistaken: they have not only been generally adopted, but pirated by some persons, and even advanced as something new by others, many years after I had published them. In order to put a stop to such proceedings I shall now enumerate those points in which surgery is indebted

for its improvements to the medical department of the army and the practice of the Peninsular war; and in doing so I trust I shall redeem the pledge given to the medical officers of the different branches of the public service in the introductory lecture to my first course of lectures on surgery, in 1816, that I would always defend and maintain their right to the improvements they first suggested or made against all encroachment."

"Previously to the termination of the war in 1813, and the appearance of the first edition of this work, the opinions of Mr. Hunter on the powers and capabilities of the human constitution were invariably received. As general principles they did little mischief; but when they came to be acted upon, the results were not found to coincide with the principles from which they were deduced. When an injury had occurred to a person in health, rendering the loss of a limb necessary, he recommended that an operation should not be performed until after suppuration had been established, a period, probably, of six weeks, which, even if the patient survived, was often found to be too late to be serviceable."

"From the failure of this practice, the contrary one of immediate amputation, became gradually more general during the war, and at its close I not only advocated and established the propriety of it, but examined the reasoning on which Mr. Hunter's opinions were founded, and I trust have proved it defective. That it was so ought indeed to be presumed, when the facts were found to be opposed to the reasons."

"It was not, however, on the single point of amputation that this reasoning led to error, it embraced the whole subject of inflammation and its consequences, which I believe can only be consistently viewed on the principles regarding the human constitution which I have advanced. The variations in the nature and appearances of erysipelas may through them be more easily comprehended, and the treatment of mortification more scientifically undertaken. The Baron Larrey has shown, in opposition to the received opinions of the schools, that in gangrene from wounds, amputation might occasionally be resorted to with success during its progress; but he did not explain that this was entirely dependent on the circumstance of its being local. The division I have made into constitutional and local mortification, and the practice I have indicated to be followed in the different species of gangrene, from whatever causes they may have originated, as dependent on this distinction, are improvements which many are inclined to adopt, without being aware to whom they are indebted for them. There is still, however, in some, an unaccountable slothfulness in neglecting all inquiry into this subject, whilst there is in others an obstinate adherence to the old practice, although unsuccessful."

"The practice of the Peninsular war led, however, to another important result in surgery; it dissipated that delusion which had so long obtained possession of the minds of surgeons of every description, 'that it was impossible to command the flow of blood through the great arteries.' I overturned at once this hypothesis—declared it to be visionary, and not only without foundation, but the reverse of fact. On the return of the medical officers of the army to London, in 1814, it was not a little amusing for them to hear teachers of surgery gravely informing their students that amputation at the shoulder-joint was a most formidable operation, on account of the impossibility of effectually preventing the flow of blood through the arteries; and when they did notice amputation of the hip-joint, it was only to declare it a murderous operation. What is the state of things now? What has the short space of twelve years done for this branch of surgery? Why almost too much. The facility with which these operations can be performed, and the safety which attends them, has been shown, and all alarm has been banished from the minds of surgeons on these points. It is now to be feared that they may become unmindful of the precepts I have laid down demonstrative of their necessity, and recommend them to be performed when others less important might suffice."

"The practice of the Peninsular war was decisive on many other points. It overturned the application of the theory of aneurism to the treatment of wounded arteries, and my paper on wounded arteries, published in 1811 in the new *Medical and Physical Journal*, demonstrated the necessity which existed for performing the operation at the wounded part of the vessel, and not at a distance. It showed, what is not yet well understood by many, that in no case (and this is without exception) should one ligature above the wound in an artery be depended upon, but that another should be applied, if possible, below it."

"I have proved from official documents that the great dread entertained of secondary hemorrhage in gun-shot wounds was groundless, whilst the practice in all cases has been established on more certain principles than before."

These and many other minor points I do not think it necessary to notice. A careful examination of the books which existed at the commencement of the Peninsular war, and a comparison of them with the observations there made on the same subject will show in what part the alterations and improvements have taken place, whilst the work, from its continued reference to the different periods of the war, demonstrates the fact of the particular time at which each of them was established, if it does not mark that at which they originated"—June 18, 1827.

The experience of the last thirty years in London, during which time I have enjoyed a share, I fear beyond my deserts, of hospital and of private practice, has confirmed the accuracy of these statements, and although I trust some improvement will yet take place in many until they attain perfection, I shall not be disposed to abandon one of them until a superior degree of information on these points be shown, which at present I do not anticipate, but which I shall most gladly acknowledge.

There is not, in fact, one word in that preface which is not true. Since 1827 nearly all my old friends and fellow labourers have passed away. I am the more bound to protect their memories. There are none to be annoyed by any stories I may now tell, by any errors to which I may allude. They have long since expressed their sense of the services they were pleased to say I had rendered them by my records and lectures, in the kindest and most liberal manner, and although I have been careful to claim little as personal to myself in all I have written, or shall do in what I have yet to write, or to say, no one of them has disputed, nor will any of those who remain dispute any assumption I may make as to how much or how little is my own.

Professor of Anatomy and Surgery to the College of Surgeons during the four years ending in 1831, I published the principal part of the lectures I had delivered during that time: On the Diseases and Injuries of the Arteries of the Human Body; on the Operative Surgery of the Eye; on some Points connected with the Anatomy and Surgery of Femoral and Inguinal Hernia; on the Anatomy and Diseases of the Urinary and Sexual Organs. In 1833: Lectures on the Treatment of Compound and Gunshot Fractures of the Extremities; on Excision of the Head of the Thigh-bone, the Arm-bone, and the Thigh-bone. In 1841, again Professor of Anatomy and Surgery to the College: on Injuries of the Head affecting the Brain. Very early I had recorded an improved method of Treatment of Syphilitic Diseases without Mercury, &c. Some of these books have gone through three editions, and most of them are out of print.

In the course of the lectures I am about to give in this and the ensuing year, I hope to be able to draw your attention to all the points I have hitherto omitted, and to advert to many of those I have noticed which appear to be of most importance. I shall begin with the injuries and wounds of arteries, including the operations required to their cure, with the hope of attracting the attention of surgeons and students more fully to the essential points to be observed in their treatment. These will be followed by an inquiry into the wounds and injuries of the chest, the abdomen, and the pelvis, with the operations required for breaking up, and for extracting a stone from the bladder.

It may be, in conclusion, some satisfaction to you to know, and it is not less satisfactory to me to declare, that none of the opinions I have advocated on behalf of my old friends, most of whom are no more, are disputed or disallowed by any of my colleagues of the Court of Examiners of the College of Surgeons, as far as I am at present aware. There is no practical point positively recommended which all of them have not admitted, and have required all students to acknowledge, up to the retirement of my old friend, Mr. White. That some of these opinions may hereafter be found capable of improvement, and requiring alteration, I am willing to admit. All I desire of you now is, that you will believe, until opportunities for observation shall occur, which may enable you seriously to doubt.

A Course of Lectures on Hernia,

By JOHN FLINT SOUTH, Esq.,

Surgeon to St. Thomas' Hospital, and Professor of Surgery to the Royal College of Surgeons.

(Delivered in the Theatre of the College, and revised by the Professor for the MEDICAL TIMES.)

Lecture I.

(Concluded from p. 12.)

Can a Rupture be cured spontaneously?—Cloquet's Opinion, Professor South's Views. Is there any Mode of Treatment which holds out reasonable expectation of a permanent Cure? Operations proposed and attempted for this purpose; Bonnet's Method; Mayor's Operations; Velpeau's Injection plan; Observations on Two Cases, by Demeaux; Effects of Continued Pressure—Advice of Langenbeck, Boyer, Lafond, Raven; Ancient Methods—Paulus Œgineta, Franco, Ambrose Paré, Guy de Chauliac; Other Methods Proposed by Petit, Freitag, Richter, Graefe, Walther, Schreyer; Actual Cautery applied by Paulus Œgineta; Arabian Operations; Opinion of Monro Primus on the use of Caustic; Kein of Vienna; Tying the Cord and Sac, practised in the Middle Ages; Removal of the Sac, proposed by Lanfranc and Bertrandi, and practised by Astley Cooper; blocking up the mouth of the Sac, practised by Dzondi, Jameson, Gerdy, Bransby Cooper, Signoroni, Wutzer, Belmas, and Malgaigne; Professor South's Opinion of these Operations.

It is a very interesting and important question, whether a rupture can be cured spontaneously? Cloquet asserts that it can, by the spontaneous return of the rupture-sac into the belly, in four different ways. First: by the contractility which the sac possesses, in common with other tissues, which continually tends to its restoration upon itself after distension, and is occasionally sufficient to produce its gentle and gradual return. "The sac, then," says Cloquet, "takes a retrograde movement to that of its formation; the peritoneum passes from the ring towards the parts it had left; that portion of it which had been drawn towards the ring, without passing through it, pulls the neck in every direction, which expands, turns out in some degree, disappears, and is at last effaced; the sac unfolds, and again covers the wall of the belly near the aponeurotic opening. The neck of the sac which was last formed disappears first, whilst its bottom disappears last, and with great difficulty; so that the reduction is often incomplete. When a rupture has been thus reduced, the remains of the neck are sometimes observed at a little distance from the ring, in the shape of irregular stigmata, whitish and more or less opaque. The peritoneum which formed the sac is restored to the abdominal wall. * * * Sometimes these sacs are so completely effaced, that no trace of them can be found in the peritoneum covering the ring, by which they had escaped; the only indication of a rupture having existed at this spot, being a cellular whitish empty pouch arising from the aponeurotic ring. Secondly: by the closure, the gentle and insensible contraction of the cellular tissue, external to the sac. The other tunics may concur also; but their action appears weaker and less demonstrable. * * In this case the peritoneum presents at the top of the ring irregular prominent folds analogous to those of the mucous membrane of the stomach during the contraction of its muscular coat. Thirdly: by the displacement of the peritoneum from the abdominal walls from various causes, as

in two cases of direct inguinal rupture, in which, in consequence of retention of urine, the peritoneum covering the bladder was raised nearly to the navel —by enlargement of the womb by pregnancy or by any other cause—by adhesion of the omentum, or intestine to the hernial sac—by a large quantity of fat collected between the peritoneum and wall of the belly, by the dragging of another sac which has formed in the neighbourhood of the former. Fourthly: by the contraction of the cremaster muscle, "the two fleshy bundles of which act upon the sac pretty much as the two bellies of the digastric muscle effect the direct elevation of that bone."

The spontaneous subsidence of the peritoneal or true sac of the rupture from either of these causes, or in either way described by Cloquet, appears to me extremely doubtful, and very improbable, excepting perhaps the third, in which the original sac is said to be retracted by the descent and enlargement of a second and subsequently formed sac. That this is possible cannot be denied; but the production of a second sac, especially in the immediate neighbourhood of one already formed, is so rare, that it can hardly be presumed on as a cause of spontaneous cure

If it be admitted that a rupture is rarely cured, except in young persons, by the ordinary use of a truss, and that its spontaneous cure is scarcely to be expected, the question then arises, must the person who has been attacked with this inconvenient, and it may be, dangerous disease, be left without hope of other than a palliative and not unfrequently inefficient remedy, or is there any mode of treatment which holds out reasonable expectation of permanent cure?

Surgeons have from an early period sought to effect this object in various ways, many of which have been accompanied with considerable danger, and scarcely any attended with success, as may be presumed from the great variety of plans proposed, and the modifications with which they have been carried out.

The greater number of the modes of treatment for effecting this—THE RADICAL CURE—have purposed the obliteration of the mouth or neck of the sac by adhesion, either by quick union, or by granulation, and a few by blocking up the passage into the belly by a plug of skin.

1st. The most simple and lenient treatment is that of continued and considerable pressure with a pad upon the mouth and neck of the rupture-sac, the contents of the sac having been first returned, and the patient kept in bed upon his back for several weeks, whilst the pressure is continued. To render the pressure more effectual, Langenbeck advises the application of a conical pad upon the abdominal ring, into which it is to be kept thrust by the pad of a common truss, till ulceration of the skin takes place, when the conical pad is to be removed, the sore dressed with lead ointment, and the truss to be reapplied for at least a month. The irritation of the skin which is excited for the purpose of producing inflammation of the cavity beneath, is by some kept up and increased by the application of spirit of turpentine or blistering ointment, or even of caustic contained in a hollow pad. To render the pressure more certain and severe, Raven recommends the use of an apparatus by which the pad can be screwed down tightly upon the part, and wetting the pad with alum wash. Other astringent remedies as bark, oak-bark, tormentilla, gall-nuts, and the like have also been employed to contract the skin, and to bring the walls of the sac together, and induce their union.

2nd. The ancients attempted the cure of rupture by cutting through the skin upon the swelling to the extent of three fingers' breadth, removing the membranes and fat, till the peritoneum was exposed, and then, having returned the contents of the sac into the belly, the peritoneum was raised with the point of a knife, and tied first on one and then on the other side without either cutting it away, or the testicle. This practice is described by Paul of Ægina, as old in his time. Subsequently the sac and spermatic cord were included in one common ligature, but this was afterwards improved on, by dissecting down to the sac, separating the cord from it, and encircling the sac with a golden thread, which was drawn sufficiently tight to close the cavity—an operation dignified with the name of the "golden puncture." The same was done by Ambrose Paré with a leaden thread, and this has been in modern times superseded by the use of waxed threads. Another mode of obliterating the sac was that of sewing it up with the glover's stitch, which was called the "Royal stitch."

The radical cure of rupture upon the principle of bringing the sides of the sac together, and promoting their union by inflammation, has also been attempted within the last few years by Bonnet and by Mayor.

Bonnet, after reducing the rupture, grasps the scrotum as close as possible to the abdominal ring, and, separating the sac and spermatic cord from each other, by nipping the thumb and forefinger tightly between them, passes a pin thrust through a piece of cork in front of their nails, behind the coverings of the rupture, close to the suspensory ligament of the penis, from above and behind, forwards and downwards till the cork touches the skin, and the point of the pin penetrates below, and is received into a second piece of cork, upon which it is twisted so as to produce slight compression of the included parts. The spermatic cord is then confined by the thumb and finger closely to this pin, after which a second pin, similarly headed, is passed about six or seven lines to the outer side of the former, and parallel to it, and being thrust through the skin, is fixed also in a piece of cork. Suppuration usually comes on about the fourth day, and the pins require removal between the sixth and twelfth, in proportion to the degree of inflammation set up. Three weeks or a month are considered sufficient for the cure. This operation does not appear to be very hopeful, as it can scarcely be supposed to produce adhesion of the inside of the sac.

Mayor's operation is a modification of Bonnet's. Having very completely returned the rupture, and passed the finger into the abdominal ring to ascertain its size, as the larger it is, the longer, wider, and more extensive must the fold of skin be; he marks the middle of the gaping ring with a pen and ink, varying the direction of the mark, so that it may be slightly oblique from above downwards, or parallel to the mesial line, according as the rupture is crural or inguinal, umbilical or ventral, and its length corresponding to the ascertained or presumed diameter of the ring, behind the upper edges of which it should extend from three to five lines, and the same distance beneath the lower, according to the bulk of the rupture. He then grasps with both hands a portion of skin on each side of this mark, which is to be raised till the ends of the mark are completely above the finger-ends, whilst an assistant thrusts a needle armed with a waxed double thread, which is guarded at the other end by a piece of sponge, bougie, or wadding, to serve as a knot, and thrusting it through the folds beneath the surgeon's nails, draws the double thread up to the knot, and then, separating the two threads, ties them upon another piece of sponge or bougie on the other side, and thus makes a quill suture. The number of stitches varies from three to seven, according to the size of the rupture. Their object is to produce adhesive inflammation around and within the ring. In slight cases no more is requisite, but otherwise slight compression may be made with a truss. The sutures are left in for eight days or longer, and Mayor does not meddle with them until the patient complains, and is never in a hurry to withdraw the threads.

3rd. Other surgeons have cut into the sac, as in operating for strangulation, and treat it with a dressing of lint, and pressure with a truss; or have scarified the mouth of the sac; or even introduced tents of lint, as advised by Dionis, and practised even of late by Graefe and Walther.

4th. The adhesion of the sac has also been attempted by injecting wine, on the authority of Schreger, as in the cure of hydrocele; or its inflation with air—the mouth of the sac in this case being closed by pressure.

Velpeau, having ascertained, as he believed, that congenital hydrocele might be cured by injection without danger, thought it probable that a rupture might also be safely cured by the same means, and accordingly in two cases of congenital entero-epiploic rupture, an acute hydrocele having appeared a few days after the return of the bowel, he punctured the swelling, in one case drew off eight, and in the other six, ounces of serum, and in its stead injected three drachms of tincture of iodine with three ounces of water; no inconvenience occurred, and three months after there was no apparent return of the rupture. Thus encouraged, Velpeau employed the iodine injection in a case of inguinal rupture, at the same time carefully compressing the abdominal ring to prevent the fluid passing into the belly. After moving the part about, so as to apply the injection to the whole inside of the sac, it was drawn off by the canula. The results were precisely similar to those of hydrocele so treated. Thus far Velpeau; but in two cases mentioned by Demeaux, which were managed on this plan, there was good proof that the injection had never entered the rupture-sac at all; in the one the patient went on well till the twenty-fifth day when he was attacked with acute rheumatism, which was followed by general dropsy, and he died five or six months after. In the other case numerous abscesses formed in the scrotum, and at the top of the inguinal canal, and the patient was in very great danger; he however recovered, but the rupture was uncured.

5th. The use of the actual cautery appears to have originated with Paul of Ægina, or, at least, he speaks of it as a more modern practice, and more in vogue in his time, than tying the sac; his method of doing which has already been mentioned. He directs that, after marking the part to be destroyed with a triangle, a white hot iron should be applied on its middle, and there kept till the fat is reached, but not deeper, lest the peritoneum should be burnt; onion and salt were then to be rubbed into the eschar, and for some days after such remedies applied as would induce its separation, and thus the cure be effected. The Arabian physicians, according to Avicenna, exposed the peritoneal sac, and, without opening it, cauterised the abdominal ring deeply. Subsequently Franco opened the sac, and, lifting it up with a dilator, cauterised the peritoneum within, as high as he could, with the actual cautery having the testicle as a *pierre de tracque buté*; he then cauterised it well all round, but not so deeply as to destroy the spermatic vessels.

Modifications of the Arabian operations have been employed in modern surgery. Monro primus speaks of caustic having been applied to the skin, "without, as far as he could learn, any rule to know when it had eroded deep enough. If the eschar were too superficial, the design of the operation could not be answered; if the caustic eroded too deeply, the spermatic vessels would be destroyed." And he continues, "I have been assured that after this operation was performed, the testicles of some children, who had undergone it, shrivelled away daily, so that they were effectually castrated." He then says that the object intended may be carried into effect "without any risk, by pinching up the integuments over the ring, and then making a longitudinal incision some inches in length; the middle of which ought to be over the ring, the depth of it such as to bring the spermatic cord into view; then, by the lunar caustic, small quantities of the common caustic, or other escharotics rightly applied, destroy the fatty cellular membranes in the ring, and under the skin; after which hasten a cicatrix by the application of ardent spirits, or of tinctures made with them; and by this endeavour to make the cicatrix adhere to the tendon in the way cicatrices generally do to bones, part of which has cast off where there has been an ulcer of long standing near them. By lying a-bed to prevent the viscera coming out, during the time of the cure, which allows the ring of the muscle to contract, and by the cicatrix, I have seen patients walk afterwards without the bowels falling out, though they wore no bandage. But this cure is not to be depended on, for though the new flesh which sprouts out from cellular substance suppurating, appears at first firm, yet it afterwards becomes as mere cellular tissue as anywhere else. Thirty-five years since Monro's operation was revived by Kein, of Vienna, with the variation of cutting down to the sac on one day, and on the following, applying a paste of one part caustic and two of powdered gum arabic mixed with water, which was repeated three or four times during the course of the cure.

6th. Tying the spermatic cord and hernial sac,

and cutting off both testicle and sac below it, was practised in the middle ages; but Franco proposed his operations for the purpose of doing away with the awkwardness of castration in these cases. As to the removal of the sac, proposed by Lanfranc, and in modern times by Bertrandi, Astley Cooper cut it off, by way of experiment in one instance, but it was not followed by inflammation of the peritoneum, which Velpeau feared.

7th. The operation of blocking up the mouth of the sac with a plug of skin was first proposed by Dzondi, who partially detached a flap of skin, and then, cutting open the abdominal ring, thrust the flap in, and there healed it.

A similar operation was performed by Jameson of Baltimore, on a young woman, who, having previously undergone the operation for a strangulated femoral rupture, had a recurrence of the disease, and was determined to run any risk for its perfect cure. He made an incision through the skin and fatty structure, down to the fascia of the thigh, a little to one side of the centre of the femoral aperture, and a little obliquely upwards, and a second incision beside it, by which he cut loose a lancet-shaped piece of integument, the widest part of which was fully three-fourths of an inch broad, and two inches in length, its largest diameter upwards and downwards, and most of the tongue-like flap below the aperture; the wide end down and cut loose, and the upper end attached to the skin, over Poupart's ligament, by which connexion this flap was to be sustained. The fascia being now cut, and the hernial tumour returned, the thick end of the flap was forced into the femoral aperture. The skin on either side was then drawn over the flesh, and united by three or four sutures. Vomiting and restlessness were troublesome for a day or two, and the outer skin did not heal in its whole extent by the first intention; still it healed in considerable part, and the flap contracted into a hard knot over the aperture; and thus was it closed, so as to prevent the return of the disease, to the best of Jameson's knowledge.

Gerdy plugs the mouth of the rupture-sac by thrusting up a portion of the skin, so that it has a not inapt resemblance to a half-inverted glove-finger. Having returned the contents of the rupture-sac, and the patient lying in the horizontal posture, he puts his finger on the skin at the origin of the scrotum, and pushes it up to the abdominal ring, and even into the inguinal canal, as far as possible, leaving the spermatic cord behind. He then carries along his finger to the top of the intended pouch of skin, a curved needle, fixed in a handle, with an eye near its point, armed with a double thread, thrusts it through the double skin forwards till the eye appears, when one end of the thread is drawn out, and the needle being retracted into the pouch, is a second time thrust through the doubled skin, at the distance of a few lines from the former stitch, and the other end of the thread having been freed from the needle, the latter is withdrawn, and the intruded pouch of skin thus left enclosed in a loop. Each end of the double thread is then separated, and tied upon a piece of quill, so as to form a quill-stitch. Generally one such stitching is sufficient to retain the intruded skin, but sometimes it is necessary to repeat the process on each side of the first-tied portion. The pouch of skin is then to be freely bathed with caustic ammonia, till the scarf-skin has been removed, and upon the external surface a pad, smeared with ointment, is to be confined with slight pressure. This completes the operation.

The application of the ammonia produces smart inflammation and suppuration in the course of three days, and the sore surfaces of the skin touching each other, soon adhere, and in about sixteen or eighteen days have united, and the plug is permanently fixed in its place. Gerdy recommends the removal of the threads on the third day, when the suppuration is established; but it would be preferable, perhaps, to leave them till they begin to ulcerate, after which time they no longer confine the skin. The patient should be kept on his back for at least four weeks after the operation, to allow the perfect recovery of the parts. The plug of skin at first appears externally as a swelling, but gradually subsides, and the cure is perfected.

Gerdy speaks of sixty-two cases treated by his operation, four only of whom died; one from pleurisy, excited, it is presumed, by the cold applications used to check the inflammation of the inguinal region; another from previous organic disease.

I am not aware that this operation has been performed in England, by any one, except Mr. Bransby Cooper, who states that the patient, after his getting up, had a slight return of his rupture.

Signoroni has modified Gerdy's operation, by thrusting up the skin with a female catheter, and fixing it with three long hare-lip pins, four lines apart, and forming on each the twisted suture. This operation he calls *introversion*. Wützer pushes up the skin with a hollow cylinder, which has a plate upon its surface, so that the doubled skin is received between its two portions, as in a pair of broad tongs, and the threads are passed from the inside of the cylinder, through apertures in it, then through the skin and other apertures in the outer plate.

8th.—Another sort of plugging has been employed by Belmas, which consists in the introduction of a tube of goldbeaters'-skin into the rupture-sac; adhesive matter is quickly deposited on it, and is said even to penetrate it, and cause a sort of union, which gradually becomes organised, and forms a solid mass, closing the entrance of the sac. That a quantity of fibrine may be poured out, and that it will become organised, is highly probable, but that dead animal matter should become revivified by union with living matter, is not very easily comprehended; and it is more likely that it is dissolved and discharged in the suppuration, than that it is absorbed, according to Malgaigne's notion.

The operation is performed in the following manner:—The patient having been laid on his back, and the protruding bowel returned, and retained in the belly by pressure on the abdominal ring, the surgeon lifts up the rupture-sac, and slips it about between his fingers, till he feels assured that it is completely empty. He then carefully penetrates the bottom of the sac with a lancet, and, holding the sides of the wound open with hooks, introduces a curved metallic tube into the cavity of the sac, and arranging it cautiously up to the neck, presses its extremity forwards, so as to raise the sac and its coverings at this point. He then grasps the skin, sac, and point of the tube, with the finger and thumb of his left hand, and thus steadies them, while an assistant introduces a pointed curved trocar, longer than the tube, and having screwed on its other end a ring, around which a cylinder of goldbeaters' skin is firmly tied, and of such size as to allow of its free passage through the tube, pushes it through the upper end of the tube, through the sac and its coverings, till its point penetrates through the skin. The operator then lays hold of the protruded point, and retains it, whilst with the right hand he withdraws the tube by the lancet-wound through which it had been passed. After which, the trocar and goldbeaters'-skin cylinder are drawn up till the collar comes through the upper wound. The trocar is then unscrewed from it, and a tube, of two pieces screwed together, one of which has a goldbeaters'-skin cylinder, filled with air, attached to it, and the other a stop-cock and screw, and by this lower piece it screws to the ring already mentioned. The ring and inflation-tubes being then connected, the cock is turned, and the cylinder being gently squeezed, the air is passed from it into the cylinder already in the rupture-sac, which is thereby distended; the cock is then turned, and the upper tube unscrewed and removed. In this way the mouth of the sac is completely blocked up, as the air contained in the cylinder applies it closely to the walls of the sac. After twenty-four hours the cock is to be opened, and with gentle pressure the air gradually assisted to escape, and the enclosed cylinder is presumed to be emptied in from forty to fifty hours. The ring is then to be gently drawn a little out, cut off, and graduated pressure applied and continued for fifteen days, to secure the success of the operation.

Of the several operations just mentioned, I have great doubt which or whether any one is feasible, excepting the most simple—compression; and, indeed, even with reference to it, instances have occurred in which death from inflammation and gangrene has ensued. From the experience of English surgeons of late years, nothing is to be gathered; for surgery, in this country, is little disposed to sport with human life, or to perform new operations, but on rational grounds. Castration, burning or tying the sac, with or without including the spermatic cord, are now merely matters of surgical history, and would scarcely be entertained by any one; and, indeed, in regard to the various kinds of plugging the mouth of the rupture, or pinning the sac together to promote its union, even the French surgeons have considerable doubt of their success. For although Velpeau observes that up to the present time he cannot perceive experience has definitively pronounced against attempting the radical cure of rupture; and that, on the contrary, he is disposed to believe that modern surgeons, justly alarmed by untoward exceptions or inexplicable coincidences, are too much prejudiced to bring their judgment to the consideration of a remedy so important, and which should be submitted to fresh trials before its decided rejection, yet, nevertheless, in passing in review the several operations proposed, there is not one to which he does not oppose reasonable doubts and objections, except scarification of the neck of the sac, to which he would give the preference if he wished to attempt the radical cure of a rupture.

As to Gerdy's operation, which has been considered the most successful, Breschet states that in several instances it was unsuccessful, and Chelius has witnessed a similar result. And Malgaigne observes that it does not obstruct a fourth of the canal, and that it can only transform an external into an interstitial rupture. He concludes his remarks on this subject by saying—On the whole he should even consider it as little prudent to attempt an operation so hazardous, when the same object can be attained by pressure—a measure always innocent, frequently efficacious in children and which in his opinion would be equally so in adults, if properly applied. I have seen, says he, an inguinal rupture cured in a twelvemonth, in an old man of sixty-eight, by complete obliteration of the inguinal canal effected by simple pressure.

Clinical Lectures on Typhus Fever,

By Dr. Corrigan.

Delivered at the Whitworth and Hardwicke Fever Hospitals, Dublin.

Lecture II.

Analysis of Fever (continued); Lesions of Functions of Nutrition, including Assimilation; Secretion and Excretion, signs of; Urine, signs from it; Principles of Treatment.

We shall to-day, Gentlemen, proceed with the consideration of fever, in lecturing upon which I have pursued a method different from that usually adopted.

In dividing fever into lesions of functions, I took up, first, the analysis of the circulating functions, and endeavoured to determine for you the treatment adapted to that particular lesion. Following up the same plan, I shall to day take up the analysis of the function next in order.

I would first direct your attention to the appearances presented in this specimen of urine. On the addition of nitric acid, you perceive an immense number of beautiful crystals begin to form instantaneously; even as I go round with the specimen, you see them rapidly shooting. Keep your attention still fixed upon the fact with which we set out, because from it, as the starting point, almost every observation to be made springs, namely, that the presence of any organic disease is not necessary to the production of fever. Keeping this fact in view, and strictly following up the same principle of analysis, we come now to the consideration of one of the elementary functions of the body—one of still more importance to animal existence than the function of circulation itself—one upon which, in fact, both animal and vegetable vitality mainly depend. I speak of the function of nutrition, in which are included secretion, excretion, and absorption. Suppose that, without going any further in our analysis of fever than we did on the last day,

you were to ask, what, added to a case of typhus fever, such as I then described, consisting mainly of a lesion of circulation, would constitute an aggravation of it? The answer would certainly be—a lesion of the function of nutrition, including, as I have just observed, secretion, excretion, and absorption. But what means have we of determining the existence and extent of that lesion? In all cases of fever possessing at all an aggravated character, there is this particular symptom:—loss of appetite; but there is superadded to this symptom, where the fever becomes aggravated by lesion of the nutritive function, not alone loss of appetite for solid food, but for fluids also. We ask a patient, is he thirsty? and the question is far from being an idle one, for by the answer we determine the amount of lesion under which this primitive function is suffering. The nurse tells you "he is not as thirsty as he was yesterday, he takes no drink unless it is pressed upon him." What does this tell us?—It tells us plainly that the function of assimilation, which is a part of the elementary nutritive function, is in a state of lesion or depression of energy. With this lesion of assimilation we invariably have a dry tongue, a symptom which, in any case of fever, is a matter of consequence, because, conjoined with others, it tells us that the function of secretion is also arrested—the secretion which should naturally take place upon the tongue is absent; the healthy secretion of the mucous membrane generally is absent, as is evidenced by the dry tongue and gums, and the sordes upon the mouth and teeth. We look upon the return of moisture on the tongue as a good sign, because whereas lesion of this function has existed, the moisture tells us there is an approaching return of its activity. A person in typhus fever may die, though the tongue be moist, because he may die without this function being much involved, but where it is involved, the fever is necessarily much aggravated. We examine the urine, because it is an indication to us of the state of the function of excretion, an important component of the great function of nutrition.

In support of these views, I shall contrast the two following cases:—

Donnelly, aged nine, was admitted on the 20th of March, suffering under typhus fever, of which he had been then three days ill, so that the fever is now of sixteen days' standing. It commenced with shivering and pain in the back. The patient lies on his back; sleeps badly; tongue dry and brown; mouth covered with sordes; abdomen soft; skin hot and dry; pulse very quick, up to 152; urine slightly acid, not albuminous, and of the low specific gravity of 1011; when held up to the light it presents a clouded appearance, which latter is caused by the presence in the urine of the epithelium, the cuticular lining of the mucous membrane, the specific gravity is low from the comparative absence of the various salts and urea; 1000 grains of urine at this specific gravity 1011, containing, according to Dr. Christison's tables, only 25 grains, or 1-40th, of solid matter, healthy urine containing nearly double the proportion. These characters of the urine, taken in connexion with the dry tongue and gums, and absence of thirst, together with the sordes, all together establish, as I have said, the existence of a lesion of that primary function nutrition; showing that we have to contend not alone with lesion of the circulating function, such as I described it to you on the last day, but also with that just now described, the whole constituting typhus fever in the severe form.

The next specimen of urine is that of the patient Hodgins, lying in the lower bed at the left hand side of the ward. He lies on his side; he is maculated, too, but his tongue is moist, and, on examining the urine, we find it presenting characters exactly the opposite to that last examined. It has a specific gravity of 1030; 1000 grains of it containing, according to the same tables, 70 grains, or about 1-14th of solid matter, being very nearly three times the quantity contained in Donnelly's urine; there is not the cloud in it which you saw in the last, but it is muddy. To obtain a deposit of nitrate of urea from healthy urine, it is necessary to evaporate it to one half, and let it stand for some hours on a stratum of nitric acid; but, in the specimen first shown, which was a portion of this urine (Hodgins'), you observed that the nitric acid was hardly added when masses of beautiful crystals of nitrate of urea were formed. What do we infer from the characters exhibited in the urine I now show you, that of Hodgins, in which the specific gravity amounts to 1030, and with the muddy deposit which you see at the bottom of the vessel? We infer that the secreting function exists to an unusually active degree. But there is even more solid matter in this urine than that indicated by the specific gravity; for the muddy deposit will (if I am right in supposing it to consist of lithate of ammonia) redissolve on the application of heat [a portion of the urine in a test tube was held over a spirit-lamp so as to heat only the upper half, which rapidly became clear and transparent, while the lower portion, unheated, remained muddy and thick]. It is soluble, you know, at the moderate temperature of the bladder, but deposits soon after the urine cools. You now see the object of placing aside the urine in cases of fever, namely, that you may be able to determine, by the appearances I have described, the state of the secreting function. As long as the urine presents the appearances observed in the case of Donnelly—high coloured, cloudy, and without a deposit—so long—no matter what the other symptoms may be—will your patient be in an unsafe condition; while, on the other hand, if the urine becomes clear on being heated, it is evidence that the function of secretion is resuming its activity, and your patient is, probably, about to get well. The nurse, or other persons about the patient, tell you he is more thirsty than he was yesterday, and they look upon that as a sign of increase in the fever, but I know from frequent observation that it is not; on the contrary, it is a sign which often precedes by some hours the amendment I allude to; in other words it tells you that the function of absorption has again commenced. Again, if you are told there is little or no thirst, you may look out for an aggravation of the disease; this symptom may be classed in the same category as the loss of appetite, &c. The term crisis, as applied to a particular period in the progress of fever, is a word which may properly be applied here, the meaning being just what I have explained to you, that the elementary function has resumed its activity.

You can readily understand with the complete arrest, or deficiency to a great degree, of this function, and without any organic disease whatever, how death may, nevertheless, take place, as neither animal nor vegetable life can continue to last with any degree of activity where this function is much involved. You hear of a "crisis" taking place in fever by urine; the urine tells us of the restoration of the function of secretion or excretion. From a specific gravity of 1010, and containing merely a cloud formed by epithelium, it rises to a specific gravity of 1030, containing three or four times the former quantity of solid matter, and depositing, moreover, a large quantity of lithate of ammonia. This marks a restoration of the function of excretion, and is properly "a crisis." A curious circumstance connected with our present type of fever is its manifesting a decided tendency to remissions; in the morning, for instance, the urine may be loaded with lithates, of a high specific gravity, and contain urea in great amount, while in the after part of the day or evening, the fever again rises, and the urine becomes clouded. It is quite possible for this to happen in the case of Hodgins, who is now only four days ill, his urine containing a deposit, and with a tongue at present moist—symptoms marking activity or restoration to health of the secreting function; yet to morrow or next day the urine may become high coloured and cloudy, manifesting a relapse of the fever. This is an occurrence which frequently happens in inflammatory fever as it is called—a fever in which lesion of the circulating function is marked by a more than usual rapidity in the passage of blood through the capillaries, with a hot skin and high coloured urine, and in which, after three or four days, a deposit takes place, when fever of a different character, marked by clouded urine and maculæ, frequently becomes superadded or supervenes upon the original attack.

Having mentioned these facts, I shall now draw your attention to Hayden's urine (a patient who also came from the workhouse) he lies heavily in bed, and seems seriously ill; the tongue is dry in the centre, with a thin layer of mucus on it, firmly adherent, showing the absence of secretion. The urine presents the slightest possible trace of cloud, but its specific gravity is only 1010, marking the lesion of the secreting function, which, as I said, forms a part of the primary function of nutrition; the lesion of the function of circulation not being severe, in other words, constituting what is called a case of typhus mitior, having a quickened pulse, and some maculæ over the skin; the tongue, dry in the centre, slightly dry gums, and low specific gravity of the urine, mark the lesion of the nutritive function. I shall now try whether it contains urea in the same quantity that Donnelly's urine did; I should say, probably not. You observe, I adopt the same process as in the first case, in which, you remember, the urea began to be deposited before I had time to place the specimen on the mantel-piece. Here there is no appearance of the formation of crystals. Observe still that, after the lapse of some minutes, there is no trace of the formation of nitrate of urea in Hayden's urine; while in that of Donnelly there was almost instantaneously a solid mass of this substance deposited.

We come next to the case of Prunty, whose urine, I find, is of a specific gravity 1020, being not very considerably above that of Hayden; but you observe the gradual rise, from 1010 to 1030, as in Hodgins' case, marking the milder character of the fever. Prunty is now four days ill; his tongue is moist; the pulse, however, is quick. His case is an ordinary case of fever, consisting of a combination of lesions of the two functions, both very far below in intensity what is seen in Haydens' case, in which the specific gravity of the urine, you remember, is only 1010. Prunty's urine, you observe, is cloudy, and I shall now heat the upper portion of the tube, in order to compare the urine at top with that which lies at the bottom of the vessel, but you see it is entirely unaffected by heat. Upon holding it up to the light, you might at first sight confound it with the appearances seen in Hodgin's urine; but the effect of the application of heat to both at once reveals the difference, the one being muddy, the other containing a mere cloud occupying the centre of the fluid, upon which heat produces not the slightest alteration; and during the continuance of which, as I told you a while ago, no matter what the other symptoms may be, your patient is not safe. The specific gravity of the urine in this case being somewhat higher, I should expect it to show traces of urea upon the addition of the acid; but, you observe, it does not deposit with anything like the rapidity that it did in the first specimen.

Here is some of the urine of the patient Walshe, between which and that of Donnelly there appears to be some resemblance; but I think you will see that there is a great difference between them when I have applied the tests. Heat, you observe, does not produce the slightest change, and we shall now add the nitric acid; but first let me direct your attention to the last specimen, Prunty's urine, in which now, at the end of eight minutes, you observe the nitrate of urea begins to form, but very small in amount, and forming, as it were, a connecting link between the case (Hodgins) in which the nitrate of urea formed so rapidly, and some of the other specimens in which it did not form at all. Donnelly, I told you, is sixteen days ill, and that his case is a bad one; the urine of low specific gravity, with a cloud unchanged by heat. The dry tongue and gums are also so many evidences of the inactivity of the nutritive functions. We have, besides, the exceedingly quick pulse, indicating the lesion of the circulating function; we have, in fact, a compound affection of the circulating functions with that of nutrition, the latter being involved to a serious degree. To return to Walshe's urine, you observe, as I stated just now, that on placing it beside that of Donnelly, they both present apparently a clouded appearance, but, to my eyes, the cloud in Walshe's urine is not properly a cloud, but a muddiness, owing to a secretion of the lithates. This I am enabled simply to say because my eye is accustomed to detect these differences; I may be wrong, however, and we shall, as usual, apply the tests. The specific gravity of Walshe's urine is 1015. Being now heated, you observe that the fluid at top becomes perfectly clear, while that in the bottom of the test tube remains muddy.

Now, this patient (Walshe) is fourteen days ill, and to-day does not present what could be called,

with the exception of the urine, a good sign; his tongue is dry on the centre, but slightly moist at the edges; he has a quick pulse, and yet, as I say, hardly one other good symptom, I am led to say that man is recovering. A period of five minutes has now elapsed, and you see there is no trace of the formation of the nitrate of urea.

When the specific gravity of any particular specimen of urine is unusually low, it is very likely you will not find the urea large in quantity; this, however, I do not give as a positive opinion.

In drawing your attention to these facts connected with the urine, I have avoided making any very minute chemical analysis, merely using those tests which in the ordinary routine of practice are easy of application, for in ordinary practice it is quite impossible to follow up any very minute analysis. By merely training the eye, in fact, you may, I think, obtain all you require as regards the characters of the urine. On the last day I directed your attention to the characters presented by that fluid in very severe typhus, when the albumen and colouring matter of the blood pass off with the urine, indicated by the dark colour, by the sediment, and by its coagulation when heated, &c.

To-day we have hardly any evidence of the presence of the salts, the urine generally being of a low specific gravity, with little urea or salts, and with the cloud produced by the presence of the epithelium, furnishing one continuous indication of the lesion of the nutritive function, on the one hand, or, on the other, the commencing recovery of the function is seen in the copious muddy deposit of the lithates, and the excess of urea. The only indication we want is that which is furnished by the presence of the phosphates; but of this we have no specimen to-day, and we might be a long time looking for it. The characters, however, are pretty much as follow:—After the urine has lain by for some hours, we observe a pellicle at the top, as if the urine were frosted; crystals of the triple phosphate form, as it were, a skin or frost at the top, which, if you touch it with the point of a pencil, breaks and falls to the bottom.

Let us see, now, whether we derive any guide to treatment from these considerations, as in the instance of the exhibition of wine in lesion of the circulating function, to which I directed your attention on the last day. The same conflicting statements exist respecting the administration of mercury, as upon the subject of giving wine. In the different papers written upon fever, you at one time see mercury set down as a poison, and in the next paper its efficacy is advocated. For my own part, I have given it with the greatest advantage for the last few years. But what do we give it for? Not for the lesion of the circulating function with sinking. No man would be mad enough to give it in such a case as that with a view of improving the condition of the blood, upon which, on the contrary, in such cases, it would act injuriously. But turn to the symptoms I have stated to-day; look at the cases of Prunty and Hayden. We give it in such cases, because, of all remedies, it is the most powerful as a means of stimulating the elementary function of nutrition. What does it do in cases where lymph is deposited upon serous membranes? Why do we give it in peritonitis and pneumonia? Combined with other remedies, you see its action in promoting a return of secretion and excretion, and for this reason you give it when you have a dry tongue and absence of thirst, when you have urine of a low specific gravity, without salts and without urea; all joined together telling you of the existence of a lesion of this function.

You give mercury in fever, then, not in large doses which might irritate the mucous membrane, and add local disease to the functional lesion. You give it in small doses, on principles as recognised as those upon which you give it in any other disease. You combine it at one time with bark, at another time with solution of acetate of ammonia; or, again, you give it with wine to meet the lesion of the circulating function. In reference to this lesion of the function of secretion, the combination of mercury, in small doses with nitre, is beneficial. The latter is one of those remedies which stimulate the function of excretion by the kidneys, and hence, we use it in combination with the mercury; while to one or both, we add bark, either to combat the type or to meet the remission of our typhus fever. And now we have an explanation in the two lectures we have gone through, of our reasons for using, in typhus fever, the combination of wine to raise the sinking of the circulating system; blisters to stimulate the capillaries, mercury to promote the return of the function of secretion, nitre to stimulate the function of excretion, and bark to meet the type of the fever and its remission. We have yet to consider the lesions of the nervous system.

FIBROUS TUMOUR.

Although I am aware that I am very far from having exhausted the subject of my last report—viz, a description of the fibrous tumour of the uterus under the various forms, &c., in which it appears—I will proceed to give some illustrations of it by cases, as these will lead to further remarks, and thus, I hope, render those which I have already given more complete.

Mrs. A., aged forty-one, never pregnant.

January 20, 1841.—Has a large, solid, and insensible tumour springing from the pelvis, and rising into the abdominal cavity. Upon vaginal examination, it is felt filling up the pelvic cavity, just like the full-grown fœtal head, with ridges like those of sutures, but it is much harder and more immovable; the os uteri has entirely disappeared, the cervix and lower portion of the uterus being lost in the general mass of solid structure.

She has occasionally much difficulty in passing water, and is unable to go long without relieving the bladder; she has sometimes numbness of the left thigh; states that the catamenia and the bowels are regular, but complains a good deal of flatulence and distension.

Applicent. hirudines vj. tumori per vaginam quâque hebdom.

February 1 (by note). Leeches have been applied twice with relief.

22. Has had the leeches applied four times since last report; the last time they bled very freely, she thinks as much as a teacupful; besides which, she passed a coagulum nearly as large; does not want to relieve the bladder so frequently, and passes water more easily. She has lost the sensation of numbness of the left thigh.

March 13 (by note). Has applied leeches twice since the last report, the first time they bled a good deal, and made her feel languid; the second time less so; states that she feels sure the mass is smaller; has not mentioned her general health; let her do so, and continue to apply the leeches.

16. Writes that her health was never better; fancies that the tumour is larger in the morning; says that it never diminishes in hardness, but that it appears to be more movable.

Cont. hirudines.

April 10. The tumour seems to have remained quite stationary, both in size and hardness; during the four months preceding January, it had increased very quickly, but since then, if anything, it has somewhat diminished. Shortly after this she discontinued her visits.

The only point of interest in this short and cursorily drawn-up case is, the effect produced by the local abstraction of blood. There were evidences of considerable pressure exerted by the tumour in the pelvic cavity, as shown by the difficulty both in retaining and passing water, and by the numbness in the thigh; all these were very considerably diminished, and the relief was in proportion to the quantity of blood lost. The general health improved; and, from the greater mobility of the tumour, it may be supposed that its size had in reality somewhat diminished. Whilst these morbid growths continue vascular to any extent they do not attain their full degree of hardness and solidity; at least, this has seemed so to me, for, in some cases, a slight, but general, diminution of size has followed the action of local bleeding, but the mass has become much harder, and has now continued stationary, not increasing any further in point of bulk. This result of local bleeding is chiefly seen when fibrous tumour has already attained a considerable size and bulk, and is also of some standing; at an earlier period its structure is not absolutely hard, but elastic, yielding more or less upon pressure; it is composed of fibrous (or sub-cartilaginous) vascular and cellular tissues, not closely, but somewhat loosely, connected together, and evidently capable of considerable alterations of size, and probably structure, dependent on increased or diminished vascular activity and absorption.

Mrs. S., aged twenty-six, fair, married three years, never pregnant.

December 18, 1844. Complains of severe and continued pain of pelvis, and over the symphisis pubis, with darting pain in the hips and groins, and aching down the thighs; suffers pain on sitting down suddenly. Hemorrhoidal congestion; much irritability of the bladder, especially at night; is unable to hold her water long, but has no difficulty in passing it. The fæces are flattened and enveloped in mucus. The catamenia appear every five weeks, but in other respects they are natural.

Has been in delicate health for years, and always more or less subject to hemorrhage, and aching of the loins. She began to have the above pains severely about six months ago, when they were so bad as to prevent her walking.

Examination per vaginam.—Uterus forming a hard, solid, nodulated mass, which seems fixed; it is tender, highly congested, and throbbing in all directions; the cervix is soft, os closed, with a soft pulpy feel inside; behind the cervix is one nodule larger than the rest.

Examination per rectum.—The whole mass of the uterus is very tender; she attributes the pain and tenderness to copious injections with cold water which she used some time ago per vaginam.

Hirudines viij. ori uteri. ℞. Ext. taraxaci cochl., min. ½, om. nocte. ex lacte. ℞. Acid. hydrochlor. dil., Acidi nitrici dil., āā ʒij; Syrupi aurantii, ℥j; Aquæ cinnamoni, ℥iss; Misce ft. mist. cujus sumat cochl. min. j. ter die ex aquâ. ℞. Sodæ potassio-tart., ʒij; O. m. ex aquâ.

28. Leeches bled tolerably, with much relief; less pain of pelvis.

Rep. med. and hirud. ℞. Quinæ disulph., gr. ij; Ext. lupuli, gr. vj; M. ft. pil. ij., om. nocte sumendæ.

January 4, 1812. Leeches were applied on the 30th, and five bled well, with much relief; feels better in all her local symptoms; can retain her water better; has less pain above the symphysis pubis; six weeks have passed since the last appearance of the catamenia.

Exam. per Vaginam.—Os and cervix uteri *much* less painful than before; anterior portion of the uterus is smaller, softer, and less tender; but behind it a hard tumour may be felt like the fundus uteri when retroflected; it is so intensely painful to the touch that I cannot introduce the uterine sound.

Pergant Hirudines and medic.

11. Only two leeches took, but these bled well, and with much relief; feels weak, but better in all her local symptoms. Omitt. medicam. Rep. hirud.

℞. Ferri sulph., gr. ij; Extr. lupuli, gr. vj. Misce ft. pil. ij o. n. s.

℞. Acid. hydrochlor. dil., Acidi nitrici dil., āā ♏. vij; Tinct. lupuli, ♏. xx; Syrupi aurant., ʒ ss; Infus. Gentianæ co., ℥iss. Misce ft. haust. ter die sumend.

℞. Sulph. precip., Magnes. carb., āā cochl. min, o. m. ex aquâ.

February 1. Has used leeches to the os uteri several times with much relief; all her local symptoms are much diminished; general health much improved.

Exam. per Vaginam.—Less swelling and tenderness; one very large vessel is felt pulsating on the right and anterior portion of the inferior segment of the uterus. The swelling behind the cervix, before alluded to, is still painful; towards the left and posterior part of the uterus there seem to be one or two hard nodules. Pergat.

25. Has continued the medicines and leeches.

Exam. per Vaginam.—The mass is smaller and

less tender; the uterine sound passed up beyond the ordinary extent; the upper part of the uterine cavity is intensely painful when touched by the sound; pressure on the abdomen distinctly moves the sound. Pergat.

October 14. Has continued to improve; the leeches have been applied occasionally, and always with relief.

Exam. per Vaginam.—Tumour very considerably diminished, softer and scarcely at all tender. Uterine sound passed easily, but I do not think that it went so far as before; the fundus is still intensely painful when touched by it.

This appears to have been a case of fibrous tumour of the uterus, involving chiefly its posterior wall, and bulging down considerably behind, and also elongating its cavity.

When I first saw her, the symptoms indicated the existence of severe pressure in the pelvis, and a highly congested state of its circulation. The tumour presented that tense half elastic feel which gave one the idea that the finger could make some impression upon it, if its extreme tenderness would have admitted of the necessary pressure. Although its bulk and solidity were very considerable, still it did not appear to have attained that degree of hardness which is met with where the mass has been of long standing, and this circumstance, together with the strong evidences of vascular congestion, in my mind fully indicated the frequent application of leeches. Immediate relief was produced; the sufferings arising from the pressure of the mass in the cavity of the pelvis began to abate; the health improved; the portion of the tumour to be felt per vaginam became softer and less painful.

As the frequent repetition of the leeches began to affect her strength, and make her feel languid, I put her upon a course of mild tonics, with good results; her general health and strength improved, and she now bore the local bleedings with perfect impunity. In this way she continued to progress until last October, when the difference in the condition of the disease had become very striking.

I have called on my patient occasionally since the last report, and am happy to find her enjoying excellent health, and feeling, as she expresses it, "quite well."

It would be an interesting question to ascertain what is the precise condition of the tumour now that it has been so reduced in size, hardness, and vascularity. May we not fairly presume that those portions of it which are of longest standing, and which are most solid in point of structure, will now have become still more compact and hard, while they have diminished in size, whereas the other and more recent portions, whose structure is softer, will probably have diminished to a still greater degree, while they have become softer and less vascular, and that even the softest portions of them may have disappeared entirely.

HOSPITAL REPORTS.

FIRST SERIES.

Reported by J. S. FLETCHER, Esq., Student at the Manchester Royal Infirmary.

SURGICAL CASES.

CASE V.

Dislocation, with Partial Fracture of the Fourth Cervical Vertebra—Paralysis and Death.

John Jenkins, aged thirty-nine, a carter from Collyhurst, was admitted into the hospital on the 27th of January, 1845, at eleven, a.m., under the care of Mr. Ainsworth. He is a stout, robust man; his habits and mode of life have not been good, and he has been a heavy drinker. About half an hour previous to his admission he fell down a hole in a warehouse, about four feet deep, and whilst falling he caught the back of his neck immediately above the scapula, against the side of a projection, which gave him a very severe blow. At the time the accident occurred he was under the influence of liquor. He says he felt slightly sick and faint, could not move his legs or arms, and was quite unable to assist himself when he was carried to the hospital.

When admitted he had not the slightest power of moving his extremities, which lay perfectly motionless, and totally insensible to all external impressions; he was unable to turn himself in bed; he had lost all sensation in all the points below the nipple—above that point he had normal feeling, except in the arms; the right arm he had not the least power over, nor had he any sensation in it; over the left he had much more command—he could extend and flex it, but could not flex the fingers to grasp any object; he had some sensation in the arm, but not the normal amount; he was unable to pass his urine; a small quantity dribbled away immediately after the accident, but he did not feel it passing; he had no command over the sphincter ani, some fæces passed involuntarily; his respiration was very laboured, and almost entirely diaphragmatic, the ribs and intercostal spaces not moving; he was perfectly rational; pulse slow, soft and weak; surface warm; face rather flushed; countenance anxious. He had no pain in the head, but complained of a fixed and severe pain at the back of the neck, over the lower part of the cervical region, this was much increased by pressure; there was no trace of any displacement or abnormal appearance in any part of the spine.

Vespere: Symptoms same as when admitted, except that pulse is more full; catheter has been passed, and drew off a quantity of high coloured urine.

28. Had a tolerable night; slept well at intervals; complains of no pain except in the neck, which is still severe and increased by pressure; paralysis remains the same; sensation is rather more distinct a little below the nipples, but there is complete anesthesia over the other parts; he has neither sensation nor motion in the right arm; in the left it is the same; the respiration is not quite so laboured; he has not passed any urine since the catheter was passed, nor has he passed any fæces; pulse is smaller and feeble, 108; skin warm and dry; has considerable thirst and anorexia.

Vespere: Has had catheter passed; it drew away a large quantity of urine; dyspnœa more urgent; other symptoms the same.

29. Has had a very restless night; the dyspnœa has been very urgent; he breathes entirely by his diaphragm; lied upon his left side, with his head thrown back to assist in breathing; countenance is sallow and dusky from circulation of non-arterialised blood; paralysis and anesthesia remain exactly the same; the left arm he can move, and has distinct sensation in the whole of it; pulse is 109, small, and feeble; surface is warm and moist; tongue dry, parched, and furred; has great thirst, but is afraid to drink in consequence of the difficulty it causes in respiration; urine drawn off by catheter; has not passed any fæces. He still complains of fixed pain in the neck; is free from pain in the head, and is perfectly sensible. He continued to get worse, and became heavy and comatose, anesthesia and paralysis remaining, and died at four, p.m.

POST-MORTEM THIRTY HOURS AFTER DEATH.

The vertebra of the neck, extending from the third cervical to the first dorsal, were removed entirely. Upon examining them there was found to be a separation of the fourth from the fifth cervical; the fourth seemed to have been torn from its connexion with the intervertebral substance, which was torn partly through. The anterior ligaments connecting these two vertebræ were torn completely across.

The right inferior articular process of the fourth vertebra was fractured, and separated with a portion of the pedicle or lateral mass entirely from the body of its vertebra, except through the medium of the soft parts, and allowed of motion in any direction. The capsular ligaments connecting the articular processes of the fourth and fifth cervical vertebræ on the right side were entirely destroyed, being so ruptured that these two processes were not at all connected to each other, and allowed of motion in any direction. The capsular ligaments connecting the same points on the left side were also somewhat injured, but not so much so as to allow the two processes to separate. The body of the fourth vertebra seemed displaced backwards on the right side, which easily took place in consequence of its ligamentous connection being destroyed.

No other parts were examined.

REMARKS.

Fractures of the cervical vertebræ are somewhat rare, but a dislocation of these parts is still more rare—in fact, I believe there is not upon record more than one case of dislocation from accident, without some fracture having occurred at the same time. At the time this man was admitted he had all the symptoms indicating severe injury of the spinal cord very high up, but below the fourth cervical; for had it been above this, death would have been immediate from paralysis of the diaphragm, in consequence of injury above the origin of the phrenic nerve. It was evident, however, from the way in which respiration was carried on, and from the extent of the paralysis and anesthesia, that the injury was immediately below that point; but what might be the nature of the injury was somewhat uncertain, as there were no traces of displacement of any of the cervical spines, nor any crepitus; had these symptoms been present, it would at once have been clear that there was fracture, but in their absence all the other symptoms might possibly arise from a severe concussion of the spinal cord, which is less fatal than cases of fracture. The cause of the partial paralysis of the left arm, while the right was totally paralysed, was obscure previous to death, but was readily explained by the fracture on the right side, whilst, on the left, there was less displacement, and, in consequence, the upper branches of the brachial plexus of nerves escaped injury.

The displacement of the body of the vertebra without its being fractured, and the manner in which the intervertebral substance was torn through and separated from the body of the fourth vertebra, point out this as a case of dislocation; the fracture of the right articular process having occurred as a consequence of this, the bones, rather than the ligamentous structure, having given way in the displacement. The displaced vertebra was causing much pressure upon the chord; and hence we had the different symptoms present when he was admitted.

In the treatment of these cases, all the endeavours of surgeons have so far proved useless. Various plans of treating fractured spine have been suggested, such as trephining to remove the spine and arch of the vertebra; but these attempts have so far failed, and, in dislocation of the vertebræ, which it is impossible to diagnose from fracture during the patient's life, violent extension and counter-extension of the body of the patient, and placing the patient with his back across a barrel, &c., have been recommended and tried, without the least encouragement towards success. All that can be done is, to guard against sloughing, and to treat any symptoms that may arise, taking care fully to empty the bladder, so as to obviate as far as possible that ammoniacal condition of the urine which generally comes on, if the patient live long enough, and causes much disease of the bladder. At the same time that we adopt these palliative means, we must hope that nature may, in some way, repair the injury, or the cord accommodate itself to the pressure of the displaced bone, as it occasionally has done in spontaneous dislocation from disease. In injuries to the cervical vertebræ, however, there is no time for this, as they are generally fatal within a few days, as in this case; but when it occurs lower down there is more time, as they live longer; I have myself seen one case where there was evident displacement in the lower part of the dorsal region, where the patient left the hospital at the end of about four months, and had at that time more sensation in the lower extremities than when admitted.

HOSPITAL STAFF.—Deputy Inspector-General of hospitals, John Robertson, M.D., to be inspector-general of hospitals, with local rank, vice Henry Franklin, whose promotion has been cancelled. Assistant-surgeon Thomas Joliffe Tufnell, from the 3rd Dragoon Guards, to be assistant-surgeon to the Forces, vice Martin, appointed to the 87th Foot. Richard Woodley, M.B., to be assistant-surgeon to the Forces, vice Pilleau, promoted in the 70th Foot.

REVIEWS.

Abstract of Researches on Magnetism, and on certain allied subjects, including a supposed New Imponderable. By BARON VON REICHENBACK. Translated and Abridged from the German by WILLIAM GREGORY, M.D., Professor of Chemistry. London: Taylor and Walton. 8vo. pp. 112, 1846.

This is a production of no common character and consequence. It comes with all the pretensions of scientific accuracy and precision, and commends itself to one's confidence, from the unquestioned intelligence and integrity both of the author and translator. They are men of ample learning and experience, patient in the search after truth, and fearless and faithful in the expression of it. Habits of analytical investigation, and of philosophical induction, in which they have been severely schooled, render it unlikely that they would commit themselves to the freaks of visionaries, or be negligent of the orthodox means by which alone realities can be arrived at. At the hands of such men, therefore, we are prepared to receive, with every deference, announcements of discovery which might perhaps strain the credulity of others, either not acquainted with the honesty of the sources, or glad of availing themselves of the opportunity of assuming an air of philosophy by affecting one of scepticism. Of the latter class there are unhappily too many, but there is some consolation in the hope that, if they have not head enough to reach the truth themselves, they may at least have heart enough to acknowledge its value after having been introduced to its acquaintance. We submit these observations to the service of those who have hitherto assumed Mesmerism, *toto cœlo*, to be a fiction, and its advocates the victims of delinquency or delusion. No startling fact was ever ushered into the world without meeting with one adventurer or another who was impertinent enough, *sans ceremonie*, to doubt it. And it has almost invariably happened that those who have been most officious in the expression of unbelief, have been the least competent to form correct opinions of their own, or to appreciate or apply the opinions of others. In most instances the current of prejudice has been permitted to set in before dispassionate inquiry furnished any authority for inference. The scepticism of all ages, and upon all subjects, has almost invariably had for its votaries the weak-minded or the wicked These are they who have either not the means of arriving at the truth, or have no anxiety for the attainment of it. They mistake ridicule for reason, and are indifferent whether their statements be those of fancy or of fact. We have watched the manœuvres of many an opponent of Mesmerism, and have found him to be precisely what we have just said. We have never defended Mesmerism in the large—nay, extravagant—acceptation in which it has been of late introduced to the world by "experimenters," in whom the profession could properly repose no faith. But whilst, on the one hand, we have reprobated the absurdities committed by charlatans and idle adventurers, who would fain make this, as they would make others of the auxiliary sciences of medicine, subservient to unworthy purposes, we have ever supported and defended against the "mock-marvel" empirics of the equally contemptible school, those principles of the legitimate science of animal magnetism which called for defence and deference. It has been our amusement to witness the mental evolutions of many a philosophical quack attired in the cast-off habiliments of the gladiators of old, who were beaten out of the arena of disputation, and to see him use the rusty, wormy old weapons of yore, against the Mesmerism of to-day, as though the lance and target, and other such trumpery, were really his own, and not second hand affairs, stolen on the sly; and it has equally been our amusement to watch such circumgyrations in a field far too good for him, and hear the dirty eclat with which he hailed himself a victor! The Quixotism tickled us amazingly, but as it was not at that time important enough to level an honourable lance at, at this time it deserves no better rebuke than that which we now offer with laughter on our lips.

The pamphlet before us is one which will be received as of great value to scientific men generally, from the importance, novelty, and probable truth of the facts which it enunciates, and to the advocates of animal magnetism in particular, for the important bearings which it has upon their particular science.

"The author has demonstrated that magnets act on the human body, especially in certain conditions, and thus restores to the statements of the early magnetisers on this point the credit of which they had been unjustly deprived. The author's experiments are the more valuable, because, as far as the present memoir extends, he never experimented with persons in what is called the mesmeric state."

"But he goes farther, for he demonstrates the existence, in *magnets*, of two forces, one which attracts iron and affects the needle, and one which acts on the nervous system, and which he has found, *unmixed*, in crystals. This new force he is disposed to view as the true agent in animal magnetism. At all events it is so in the magnet, when it acts on the system."

"This new power is transferable from one body to another, and is conductible through matter. A body may be for a time charged with it, and this is the true explanation of the fact now demonstrated by the author, that a glass of water, as stated by Mesmer and his followers, may be magnetised by contact with a magnet, although that term is improper." (Gregory's Preface, pp. v—vi.)

Dr. Gregory very judiciously says, in anticipation of the petty objections raised by those who have only idle laughter and scorn to supply the place of reason and sober reflection who would play the bully and the braggart when science fails to serve them—who would meet scholars and gentlemen with weapons such as these never deigned to use, and would not degrade themselves by contending against—

"It is easy to object to these researches, that they have been made with persons in a morbid state, and are therefore unworthy of confidence. This is a very convenient way of getting rid of facts, far more so than that of disproving them by researches as laborious and conscientious as those of the author. But it is not a scientific method, and is, therefore, unsatisfactory." (pp. vii—viii.)

The work throughout consists of numerous and carefully-conducted experiments concerning terrestrial and animal electricity, or rather, perhaps, concerning inorganic and organic electricity, both terms being used in their widest acceptation. These experiments are so ample, and of necessity so connected, that, to enter into an analysis, or even to give a summary of them, would be inconsistent with the space we have to devote to their notice. We must, therefore, entreat the attention of the profession, and of the scientific public, to the pamphlet as it is issued to us from the hands of Dr. Gregory. It is full of most important facts, derived from careful, impartial, and continued observation, and though these facts were not elicited with any preconceived intention of advantaging the science of animal magnetism, yet do they most singularly bear in its favour, and defend it from the ridicule of those vapid opponents who would affect to laugh it out of countenance. We apprehend that these "exposers" of its "absurdity" will find some difficulty in handling to its discomfiture the weapons which Dr. Reichenbach has given them to wield, or in persuading the sober part of the profession to believe any of the mountebank grimace and jargon which themselves may choose to employ in its favour. The pamphlet before us suggests to us the idea that animal magnetism, divested of the extravagance with which impostors have invested it, is in a fair way of having its claims placed on a just and substantial ground—that only ground on which in reality any system can stand with prospects commanding and constant—that of scientific induction from well digested, well substantiated, incontrovertible premises. We cordially commend the pamphlet to the notice of our readers.

The school of medicine at Galata-Serai is making great progress. Lectures on pharmacy and on midwifery (the latter for midwives) are delivered, and autopsies are practised more frequently than formerly. A pathological cabinet, prepared by Dr. Thibert, has also been purchased.

TO CORRESPONDENTS.

A Three Years' Student and a Constant Reader *will find full information on the subject he inquires about in our last Students' Number.*

Junior *is certainly liable under the Apothecaries' Act whilst practising without their qualification. Whether the Company would exercise their right in such a case seems, however, improbable.*

S. H.—*Our next number will contain the report of the meeting of the Medical and Chirurgical Society, at which Mr. Liston brought forward the unfortunate case of Mr. Seton.*

M. B., a Former Student of University College. —*It would be hardly fair for us to give the name of a person forwarding information, to a correspondent who conceals his own, and even under other circumstances we are not in the habit of betraying confidence reposed in us. Our correspondent may rest assured, however, of the exactitude of our statement.*

Beta *can answer his own question by consulting* Walker's Dictionary.

Mr. Wilton's *memorial is proper matter for an advertisement. We should be glad to see others follow the example of the Gloucestershire Medical and Surgical Association, in memorialising the Government against the College of Surgeons—but we cannot promise to print the documents.*

Dr. Sheehan, of Fern Hospital, *disputes the opinion of a correspondent of ours, that fever hospitals increase the mortality of fever. By the report of the Poor Law Commissioners on Irish Charity, the deaths in Fevers Hospital in 1840 were only about 6 per cent: and the removal is argued to have been likely to have stayed such contagion, and also not to have increased the mortality of those attacked. The latter inference is further supported by the wretchedness of Irish dwellings. The advantages of regular attendance, ready supply of food and medicine are also dilated on by our correspondent.*

Medicus.—*The meeting of the Association is held at six this evening (Friday).*

A Student.—*The apprenticeship is indispensable.*

M. H. *is welcome to try.*

We have to thank numerous correspondents for letters on various interesting topics. Our columns are so pre-engaged that we can make no pledge of early insertion.

A Surgeon.—*The Council are again said to have stopped short in their thoughts of a new charter. At any rate, nothing effective is being done.*

THE MEDICAL TIMES.

SATURDAY, APRIL 18, 1846.

There is no greater lesson of wisdom than to know when we are well served.—DRYDEN.

THE meeting of the members of the National Association, to be held this evening (Friday, is of inexpressible import. Our hopes of an improvement in medicine are largely centred in it. We have nothing else to look to. The Government stands—self-confessed—incapable; the corporations are effete; the Profession shows no sign of movement, save through this Association. The meeting of this evening is then pretty well our all. It holds the casting vote of our fortunes, and is the arbiter of professional destiny for years. It will specifically adjudge whether our vessel shall drift rudderless, as of aforetime at the mercy of every wind of injustice and every current of intrigue, or whether—refitted, and under respectable pilotage—it shall make direct to the noble harbour of an honourable science to which all good men's wishes have so long pointed.

We rejoice to think that, if the Association be thus our sole hope, it is, at the same time, a magnificent hope. For twenty-five years we have had nothing like it. There is in it a power from numbers—an influence from character—a force from

union—all unprecedented as great. There is in it a commenced organisation which, if manipulated with due skill and courage, must collect about it the intelligence and energies of the whole Profession—materials whence may be built up that fabric of medical government, alike called for by the character of the age, and the needs of science. Two easy conditions fulfilled—the Profession true to the Association, and the Association true to itself—there is no limit to our triumph, save complete success.

Now, why is it that, amid the corrupt incapacity of our corporations, and the indifference of Government, and the immobility of a part of the Profession, we have this pleasing prospect of action, order, and improvement? The answer is not flattering, nor is it likely to be grateful to many of our readers—the mass of the Profession. It infers no great things done on *their* part; and men who perform not their own duty, do not like to be told of their obligations to those that do. Beyond, then, what has been done by the press, the chief merit of all lies with the sixty or eighty gentlemen who, consenting to form the working committee of the Association, have given time, money, and deliberation to push forward the good work. To them and their incessant labours we owe this great organisation. Without their honourable abandonment of hours of privacy and repose in response to the calls of public duty, we should now not only be without improvement in medical affairs, but without the hope of it. Whatever is good in our present position—whatever hopeful—whatever *not worse*—we owe to them, and if they fail to carry out their views, or are compelled to abandon the work they have set their hands to, we shall despair of the "republic." For, if they, pursuing their old course of deliberative, but active, wisdom, are defeated—if they, honest in design, as respectable in numbers and personal position, fail—what possible combination, more immaculate and less objectionable, can we look forward to as likely to initiate, or bring to success, a new movement? The vessel of medical reform, if not brought to harbour by them, must founder. They are not only the best, but actually the only pilots that can take charge of her.

The obvious policy, therefore, of those that hate a settlement of medical differences is to bring into suspicion and disparagement this respectable committee. Defeat them, and medical reform is retarded, and made a miserable bone of peculating contention for another quarter of a century. There never was such a union for good before—this ended, there never will be again. The true policy of the enemy, therefore, is to introduce defeat by dissension. Defeat now is a defeat total for years.

That the attempt will be made at the meeting, or rather renewed, we cannot doubt. There never was a cause without unscrupulous, unprincipled, and characterless *attachés*, ever ready to retort the antagonism of vulgar cunning for the repudiation of indignant respectability. There never also was a cause without some followers who, from wounded vanity or weak powers of reasoning, were accessible to seduction. These are contingencies that befall every great movement, but they are of import only when the movement is under weak direction, or depends on unworthy supporters. The low impostor may lay snares—the simple dupe may unwittingly help to spread them—but with a perspicacious public, with stirring men at their head, detection is sure, and indignant reprobation inevitable. But we must not speak too confidently. The interests identified with the present movement are great, it is true, and the Profession would suffer by the defeat more than can be hastily described. But we are a body—at least so it is said—incapable of permanent union—full of natural distrusts and jealousies—and ever ready to break to pieces on the first assault of any unprincipled "*manœuvrer*." The general opinion is that respectable men may work to advance our interests without securing better return than a doubt as to their motives; and that with the most obvious advantages before us we would withdraw from the best organisation on any objection trumped up by a malicious ingenuity. We are affirmed, in short, to be unworthy of that medical government we ask for—that giving ourselves up to a low system of public ethics, we have neither the public virtue to make sacrifices for the good cause ourselves, nor the fairness to appreciate with gratitude the sacrifices of those that do.

Intrinsically we believe these imputations to be libels on the fair fame of the Profession, but outwardly, and by practical demonstration, it must be owned, they are not rebutted with the vigour and decision that might have been expected. We have seen this respectable committee in the midst of the most harassing and responsible exertions for us made for months the subject of coarse and (we speak advisedly) brutal vituperation; and great as has been the disgust expressed individually in consequence, we are yet not aware that the Profession, as a body, has made such a demonstration of its feelings as the occasion fairly demanded. If public men have duties, they have also rights, and among the first of them surely is it, that those for whom they labour, should not suffer the efficiency of their exertions to be interfered with, and tamely sit by while they are subjected to all kinds of outrages as wanton as they are gross. Gratitude

> ——— is the spur that the clear spirit doth raise
> To scorn delights and live laborious days.

And it is not very pleasing to the purest minds after their toils and anxieties

> ——— The fair guerdon when they hope to find
> And think to burst into a sudden blaze

to find that they are made the subjects of an unrepelled vituperation, and in place of an ardent support meet with but a lukewarm indifferency. It is not in this way that our interests can be advanced. The only result is to throw public affairs into the hands of unprincipled persons, without character or station, who will turn them into matter of merchandise.

> Seria cum possim, quod delectantia malim
> Scribere, tu causa es, lector —MARTIAL.

A FEW more words upon the quackery of the ancients, and its imitation in more recent times.

Somewhere about the close of the thirteenth century lived Cophon, who wrote a book on purgatives. The work possessed no inconsiderable merits, but it gained him more reputation than recompense, and finding that, to please the public, and get well paid for it, he must strike upon some singularity, he essayed the adventure, and it answered admirably. He advertised a sort of aperient diet, obtained by feeding a pullet for eight days on white hellebore, and then killing it and making it into soup. The soup which he vended, though of course not prepared as he affirmed, acted as a gentle purgative, and was eagerly sought after by two very large classes of persons—those who are caught by novelty, and those who want coaxing, like children, with physic made palatable. Cophon made both fame and fortune by his ingenious device. Since his time, his practice has had multitudes of followers. Within our own recollection, "medicated mutton," peculiarly fitted for dyspeptics and consumptives, has been puffed into popularity; and *a-la-mode beef*, with a novelty of seasoning, has been vaunted as a *sine quâ non* for keeping the bowels open; whilst cathartic, lithontriptic, and stomachic soups, have been as common, and about as valuable, as continental degrees. The absurdity, however, has for the most part passed away, and left the refuse of its reputation chiefly in charge of jalap-gingerbread, and aperitive "home-baked," fermented without barm.

Something of the same school was John of Gaddesden, who was the founder of a fashion, which has never been extinct since his day, and which will most likely continue to live as long as physic may be called for. We mean the practice of never dealing in unpalatables, either of opinion or of prescription. John's phraseology was "linked sweetness long drawn out"—no matter what the disease, or how near the patient to death, John was all consolation and honeyed comfort—he talked pain out of its very existence—persuaded hypochondriacs that they were as happy as angels, and was often on the verge of cheating death of a victim, by suggesting to the poor sufferer that he was getting well fast. His physic, like his phraseology, was as agreeable as it could be, and great was the success his *placebos* met with, which were of course administered under the self-satisfying conviction that, if they did no good, they were not likely to do any harm. It is not necessary that we should pause to count over the names of the many fashionable physicians who, since John's time, have followed his example and been fed as amply.

Another, John Arden we mean, who lived about the beginning of the fourteenth century, got into immense popularity and practice by inventing an enema syringe. Before his time the custom of giving injections was not common, and the *modus operandi* thereof was very bungling. These things he remedied by the introduction of a simple instrumental contrivance, which served him so well, both at home and abroad, that he said of it, "centies pecuniam et famam in locis maxime distantibus acquisivi." Of course he made his machinery marketable by persuading the people that they were suffering from the particular ailments for which his contrivance was intended. Nothing is more easy than to make a man feel ill by telling him he looks so. This was the unavoidable weakness of one's nature that John Arden fastened on—he affirmed certain diseases to be much commoner than had hitherto been supposed, and he described their symptoms with such fidelity and minuteness, that to fail of fancying you had got some of them, was next to impossible. Forthwith piles, fistula, constipation, and stricture of the rectum, started into fashion, and came, as a matter of consequence, within the magic circle of John's healing pretensions. He caused diseases, and he cured them, and much were the people indebted to him for the skill and scrutiny he exercised in their service. A comet, like a Cape sheep, is generally thought important in proportion to the length of its tail. Regarding John in the light of either of the natural curiosities in question, he was quite a wonder in his way, for he has had as many followers as would rival the retinue of Mahomet. Mercy on us! what ailments of the nether bowel have been called into existence, and conjured out again, in our own day, by an *instrumentality* like that employed by John Arden! What fortunes, aye, and what fools, too, have been made by syringes, suppositories, rectum bougies, and other such ware! But whatever notoriety may belong to them, it is curious to find that they have no claim to novelty. Our forefathers were no wiser than we are.

Bovius was an old medicine-monger in the sixteenth century, who discovered in a "concen-

trated preparation of gold," as he called it, a cure for syphilis. He was believed, of course, and he vaunted and vended his remedy, until he found himself sufficiently enriched to do without troubling the credulity of the public any longer. Bovius had had predecessors in his particular line, but their adroitness did not equal his own, and we are inclined to regard him as the illustrious head of that horde of impostors, who, in his *specific* department, have contrived to offend the moral decency, and pick the pockets, of mankind, with impunity, from his age to the present. Would that dupes of this execrable fraud were to be found no longer! Would that our youth, to whom the artifices of these adventurers are addressed, would learn to read in their very trickery the evidence of their imposture!

Stulte, quid o frustra votis puerilibus optas,
Quæ non ulla tulit, fertque feretque dies?

Botallus, who lived in the sixteenth century, failed for a long time to get into practice, notwithstanding all his learning and professional skill, which he possessed in great abundance, so he bethought himself to start the novel scheme of large bleeding. He accordingly announced that the plan of treating disease otherwise than as he suggested was good for nothing, and that if people wanted to get rid of their ailments in right earnest, and quickly, they must be phlebotomised on a large scale. This doctrine he proceeded to carry out to very decided lengths, and so gained the credit of being "a kill or cure man." This soon established his popularity—he became as seductive as a syren—and though he now and then bled a poor devil to death, the people did not mind it a straw, but continued to praise and pay him for the jeopardy he put their lives in. The *circulating medium* fell into greater disgrace than ever did the paper currency of this country—blood got to a discount, and nobody would be bothered with it—solidism was all the rage, and to such an extent did the mania spread throughout France and Spain, that, had it not been finally laughed out of credit by the Sangrado of Gil Blas, the population would have stood a fair chance of becoming exterminated. A few years back, the prejudices of Armstrong in favour of bleeding, enforced as they were by his eloquence, operated so potentially upon his pupils, that there was something more than a probability of the old absurdity reviving. Venesection became vastly popular, and amongst its many votaries it found not a few victims. This freak suggested another, diametrically its opposite. The public were respectfully informed that "the life of the flesh is in the blood," and on no account whatever ought it to be spilt. The cutting fellows of the old school were forthwith denounced by the "new lights" as little better than assassins and cannibals; and to make a man's nose bleed was a criminality kindred to cutting his head off. Youngsters were prohibited penknifes; the axyrite threatened to supplant the razor; and pins and needles were fast losing their popularity, from their dreadful tendency to cause punctured wounds! Any solution of continuity, even a scratch, if blood were on it, was a sight as "horrible and awful" as anything that startled the vision of Tam o'Shanter at Kirk Alloway. This absurdity, of course, took as readily as the other, because there was something new about it, and it broached no half measures, but went plump *in extremis*, as though [illegible] no doubt about it. Had these opposing [illegible] carried no danger with them, but been [illegible]ulous merely, right well might one have laughed to see humanity, yclept rational, so divided against itself, that whilst one would be bled almost to his last life drop for nothing, another would burn and boil away with a fever heat and torturing inflammation, and spare not a particle of blood, even to save his life! Such, however, was the fact—one more, added to the many instances of prejudice and perversion of which the world has been guilty aforetime. It is striking enough, but withal not strange, for both in public and professional life it has plenty of counterparts. Many a gin-shop is neighboured by a temperance hotel, and the disciples of either think the devotees of the other a strangely deluded set of beings. Not long ago, multitudes on the sick-list were being cured by swallowing the pills of a quack in such prodigious quantity that they furnished both the means and the material of evacuation; whilst equal numbers were "shuffling off" their ailments by partaking of simples in such infinitesimal quantities, that the microscope must be a very bold one that would engage to get a sight of them. At about the same distance in chronology we find cold water, inside and out, a cure for everything, providing it were used unsparingly, and nothing stronger drank in the meantime; multitudes were converted to its faith, and marvellous were the cures it performed. At this same period of time a remedy, as different from the former as light from darkness, as sunshine from shade, won its way into favour, and fairly rivalled cold water in the abolition of ailment. This remedy, which might have been a suggestion of the brains of some fervid old alchemist, parched by a furnace heat, and by custom made fond of it—this crack remedy that really seemed to convey the idea of having something unearthly about it—was neither more nor less than—— BRANDY AND SALT. Molten lead, liquid sulphur, boiling pitch, and boiling water, are all very well in their way, and for the purposes they are required to serve; but we know they have never had any human purpose in view, except in the form of punishment. How near brandy and salt may approach to these said things is best known to those who have tried it. For ourselves, we should imagine the distance to be not worth a mention; and yet it found victims who scalded and scorched their throats with it as willingly as any infatuated Hindoo whoever burnt herself upon a pile. But it was not a mere affair of scalding and scorching; it worked wonders of healing—diseases the most inveterate and intractable yielded to its influence—and though it neither restored the dead to life, nor turned old people into young, it stopped little short of doing both. At any rate, its fame equalled that of its antagonism, cold water. We leave it to the patients of the two parties to say which is the better or the worse of them.

MR. LAWRENCE.

The vote of "disapprobation" on this gentleman by the Council of the College of Surgeons is said to have been rescinded. The question, we have reason to understand, is not, however, wholly set at rest. The pot calling the kettle *black*, was not without its comedy—but the pot *correcting* itself and calling the kettle not black, is something more amusing. The Council is certainly exquisitely on good terms. Beautiful is it for brothers so to dwell in harmony.

Dr. Attilio Menucucci, of Rome, employs the juice of the urtica urens as a hæmostatic remedy, and he says with marked success. He also has recourse to it in cases of relaxation of the uterus, by introducing into the vagina a sponge soaked in the juice, previously mixed with warm water.

TRANSACTIONS OF LEARNED SOCIETIES.

SURGICAL SOCIETY OF DUBLIN.

Meeting of the 21st of March.

[From our own Correspondent]

R. Carmichael, Esq., President of the College, in the Chair.

On Puncturing the Membrani Tympani.

Mr. Butcher made some lengthened remarks on the subject of the above operation—one, he observed, which, though looked on with distrust, or altogether deprecated by many, is but too readily put in practice by others. He did not by any means assert that cases never occur in which the operation may not be called for, but he contended that they must be comparatively few, and for these very important reasons, that in many instances it is utterly impossible to distinguish between functional disease of the nerve, when not well marked, and obliteration of the Eustachian tubes near the tympanum, added to which there are the malformations of the middle ear during development, their fœtal conditions being often permanently retained.

Mr. Butcher then proceeded to support his views by a detail of cases, and began with that which had been the subject of this operation, as first practised by Sir A. Cooper. A young man, aged seventeen, was so deaf from birth as to have been unfitted for business of any kind; the fauces, too, were so imperfect as to render him incapable of blowing his nose; but the perfect condition of the auditory nerves was proved by his hearing distinctly a watch placed between his teeth, or against the bones of the head; he never had a buzzing noise in the ears. The membranes of both ears were pierced in this case, and with the happiest results, as far as we learn from the record of its cure, which, as Mr. Butcher observed, extends only to the second month after the operation,—the case, however, being one peculiarly favourable for the purpose. The results of the operation in various other cases recorded by Sir Astley Cooper, ought not, Mr. Butcher observes, to lead to any favourable conclusion respecting it, because of the deficiency in diagnosis and mode of characterising the respective cases; at least, they can become valuable only after further experiments and better diagnosticated cases. He was the more satisfied of this, too, from the fact of Dubois, following the dictates of Sir Astley, having punctured the membrana tympani four times without success in any. The want of success cannot, Mr. Butcher observes be attributed, as it one time was, to union of the divided membrane, inasmuch as Fabrizi's trochar effects the long sought for desideratum of cutting a piece fairly out. May it not, he asks, be more fairly ascribed to the sudden and unaccustomed stimulus, producing a complete insensibility of the acoustic nerve? Mr. Butcher made some general allusions to the anatomy of the membrana tympani, and dwelt upon its copious vascular and nervous supplies; its vitality, he observed, appearing to have been overlooked by rash experimenters, who seemed to have lost sight of the facility with which a destructive process, once generated in it, is propagated to the neighbouring parts, particularly to the lining membrane of the tympanum; and though inflammation of a chronic or of a strumous character often produces considerable local destruction, yet, he maintained that a vast difference in character exists between that species of inflammation and what we should expect to arise from injury, which latter is much more likely to spread to the membranes of the brain.

Mr. Butcher now detailed two cases, in which, for a day or so, temporary restoration of hearing followed the puncturing of this membrane; but head symptoms of the severest character quickly supervened and terminated in the death of the individuals. In one of these, a young man, aged twenty, complained of deafness in the right ear twelve months previous to his death, and had his tympanum pierced by a surgeon in this city. The hearing was at first slightly improved, but after three weeks, he was as deaf as before, and from this period were superadded periodic attacks of headache with loud noises, which latter were particularly troublesome; there was also a constant dull, heavy pain in the affected ear, which was

occasionally exacerbating. General indisposition ultimately set in, marked by restless nights, loss of appetite, and those periodic headaches, which now rumbled with greater or less intensity to various parts of the head; these symptoms, together with an unaccountable lassitude, constituted the history of the case, until within a fortnight of his death, at which time he was seized with rigors and all the other symptoms of fever. The head-affection now assumed a most violent character, and, notwithstanding the most energetic treatment, the symptoms gained ground, and he died.

On examination, the pia mater was found exceedingly vascular, and the ventricles contained at least six ounces of thin straw-coloured fluid; there was softening of the septum lucidum, and the thin thread-like bands of its white structure floated about in the fluid. The dura and pia mater at the middle fossa of the right side of the base of the skull were much more vascular than elsewhere, and, on lifting up carefully the middle lobe of the right central hemisphere, a streaking of healthy looking purulent matter was found, communicating with an abscess, about the size of a small walnut, situated in the anterior part of the right lobe of the cerebellum, the brainy matter surrounding which was rendered very firm. The dura mater covering the upper and under surface of the petrous bone was much thickened and rough. A small tumour, about the size of a bean, lay on the auditory portion of the seventh pair of nerves. There was no opportunity of examining the bony structure of the ear. Mr. Butcher exhibited to the Society a preparation of the brain of this case, the seat of the abscess and the small tumour being very distinctly perceptible.

The *rationale* of the case, Mr. Butcher considered, was very plain, viz., that inflammation attacked the tympanum after the operation, and was transmitted to the brain. It also bore him out, he thought, in the statement he had made a few minutes ago, namely, the difficulty of distinguishing between functional affections of the nerve, when not to any great extent, and obstruction of the Eustachian tube, high up. For in this case, evidently, the deafness arose from the pressure of the tumour on the nerves, while the surgeon clearly acted on the belief that the Eustachian tube was the part affected.

The President, in commenting upon the cases brought forward by Mr. Butcher, mentioned some instances of violent inflammation of the tympanum, attended with swelling of the periosteum covering the mastoid process, in which, after the failure of leeches and various other remedies, the most decided relief was obtained from cutting down upon and dividing the inflamed periosteum. Cases frequently occur, he observed, in which violent pain in the ear is entirely symptomatic of disease in the brain, and in which if the tympanum were punctured death would most likely be attributed to the operation. A case of this kind had been published, with others, by the President, in the *Dublin Medical Journal*, for 1834, with a view of introducing to the profession the vast advantages resulting from the exhibition of mercury in inflammatory affections of the brain. The use of this remedy, then first suggested in those cases, became generally adopted in this country; but some years after he (Mr. Carmichael) attended the meeting of the British Association, at Bristol, on which occasion Dr. Pritchard, of that city, read a paper on inflammatory diseases of the brain, in which that celebrated practitioner recommended deep incision in the scalp, but did not in the slightest degree allude to the use of mercury, so generally employed with advantage in this country. Dr. Pritchard seemed astonished when informed of our practice, which induced him (the President) to conclude that at that period it had not been adopted in England.

Professor Jacob thought Mr. Butcher's cases particularly valuable, as furnishing two well-marked examples of loss of life from the inflammation consequent on puncturing the membrana tympani, and was only surprised, he said, that many such cases are not heard of, it being a habit with persons to perform the operation for the mere acquirement of a temporary celebrity, well knowing that the relief obtained is equally short-lived. The cases recorded in which Sir Astley Cooper performed the operation, and the results obtained, were, he remarked, but few; and though Sir Astley did perform the operation frequently, he did it in a very delicate manner, by merely passing the sharp end of a silver probe in and out of the membrane. He used at the same time to say to the pupils that a mere temporary improvement would be produced. The operation, however, obtained for Sir Astley considerable celebrity, as also the Copley medal for his communication published in the Philosophical Transactions, though the operation was before a year found by no means to be attended with the success generally anticipated.

Dr. H. Kennedy could not think it strictly justifiable to connect as cause and effect the terminations the operation in the cases detailed by Mr. Butcher, inasmuch as he had himself seen, and many others present must have seen, similar cases terminate in a similar way, where no operation at all had been performed; besides, the most trifling operations are now and then followed by equally unfortunate results. For these reasons he did not think we should be deterred from occasionally having recourse to it, though as yet it has not been known to be attended with much benefit.

Mr. Butcher considered that Dr. Kennedy's remarks only tended to support the views he himself advocated. For if, in these cases, it be admitted that a slow, chronic inflammation of a scrofulous character exists with a tendency to spread and ultimately involve the brain, how much more likely would it not be for such an occurrence to take place, with the addition of an injury like that from puncturing its membranes, to so sensitive an organ as the tympanum?

Dr. Benson was not an advocate for the operation; on the contrary, he was rather opposed to it on principle. Neither the physiology nor pathology of the ear would lead one to hope for much benefit from the practice; nor did experience add much in the way of encouragement. Yet he did not think the cases now brought forward sufficient to condemn it entirely. Some cases might be suited for the operation, others not; and to get rid of so great a calamity as deafness, some risk might reasonably be undergone. He would ask if there be not many recorded cases in which the operation has been performed with permanent benefit, and are there many in which fatal consequences could fairly be attributed to it?

Anomalous Cases of Disease.

Dr. Durby, of Bray, felt anxious to place before the society the particulars of some cases that occurred in the Rathdown workhouse. Their violence and peculiarity led him to think they would not prove uninteresting at this particular time, when it may be apprehended that this country is threatened with a heavy visitation from disease.

A sickly boy, aged fourteen, was found, on the morning of the 23rd January, in an almost insensible state, a quantity of liquid discharges having passed from his stomach and bowels during the night; his aspect was that of a person in the collapsed stage of cholera; face pale and sunk; surface cold and clammy; eyes glassy; pupils dilated; voice husky and peculiar when he cried out, for he did not speak; the pulse about 90, and a mere thread; frequent spasm and convulsion of the abdominal muscles, rendering it necessary to have him held down in bed; frequent vomiting of a colourless glairy fluid. Hot bath, sinapisms, blisters, and other measures, entirely failed to produce any amendment, and, after sixty or sixty-five hours apparently great pain, he died, without having spoken or swallowed from the time he was first seen. No autopsy.

In a second case, a healthy boy, aged ten, first complained while at breakfast. When seen in an hour after, his appearance was that of a person recovering from an epileptic fit: face flushed; skin warm; pulse 110; pupils dilated; required to be roused before he would answer questions; complained of severe pain in the abdomen, upon pressing which he cried out. There was vomiting of a viscid green fluid, and he had neither passed urine nor fæces from the morning before; belly tumid. The head was shaved and leeched extensively, blisters and sinapisms were applied, and calomel with Dover's powders given every hour. Next day, however, he was comatose, and remained so until the 7th, when he was observed to be covered with a profuse sweat, is said to have spoken, and taken some wine, and died in an hour after.

At the autopsy, sixteen hours after, the arachnoid covering the convolutions of the brain, presented patches of lymph on its surface; the ventricles contained about two ounces of serum, with shreds of lymph in the fluid; pons and medulla oblongata coated with yellow lymph; brain firm; thoracic and abdominal viscera healthy; the latter rather congested.

Dr. Durby related several other cases in which the symptoms as above were more or less violent, followed usually by fever symptoms after a few days. The subjects were all boys, about the ages of ten, eleven, and twelve; and it appeared strange, he said, that disease should fix upon a particular class in the house to the exemption of the rest, and not depend on some special cause. Yet after investigating closely the circumstances of bedding, cleanliness, ventilation, food, &c., he could discover none.

In reply to a question put by the President, Dr. Durby said the potatoes used in the institution were excellent, being much superior to those obtainable by persons in the higher ranks of life.

The President's reason for making the inquiry was, he said, that on a late occasion—as he supposed Dr. Durby was aware—a very extraordinary affection resulting from the use of diseased potatoes was seen in the persons of a whole family brought to the Richmond Hospital.* There appeared to him to be a considerable degree of similarity as regarded the kind of symptoms at least; but the very marked feature in the cases at the Richmond Hospital was the intestinal paralysis.

On Poisoning by Oxalic Acid.

Dr. Geoghegan, the Professor of Medical Jurisprudence to the Dublin College of Surgeons, now presented, for the inspection of the Society, the stomachs of three persons, who had committed suicide by swallowing oxalic acid. Dr. Geoghegan observed that the parliamentary returns of death by poison, in England and Wales, for the years 1837 and 1838, showed that the use of oxalic acid for this purpose, during that period at least, was much less common than might be supposed, from the inclusion of this substance amongst the ordinary poisons of these countries. Knowing, however, the loose mode in which coroner's inquests are conducted, and the numerous cases likely to have been erroneously set down as natural death, the above returns can only be looked on as affording a rude approximation to the truth; yet this and the Sixth Report of the Registrar General of Births, &c., are the only documents affording extended statistical information on the subject. The following is the number of ordinary poisons included in a list of 543 cases, which come under judicial inquiry during the above-stated period:—Opium, 193; arsenical poisons, 186; mineral acids, 35; hydrocyanic acid, 34; oxalic acid, 19; mercurial poisons, 15; the whole making 482. The Registrar General records only two cases of poisoning by oxalic acid for the year 1840, a statement which Dr. Geoghegan thinks it difficult to look on as correct; more particularly as the poisoning by opium and arsenic, during the same period, appear to be evidently underrated. Dr. Geoghegan then made some remarks on the relative frequency of poisoning by oxalic acid in Great Britain and the continental states—a comparison, he observed, difficient to carry out, as far, at least, as regards France, the returns from which country only refer to cases brought to *trial*, excluding consequently many instances of death by this substance, which for obvious reasons, however, is seldom selected as the instrument of murder.

By the kindness of Drs. Leesom and Mason, the gentlemen who had conducted the respective inquiries in these cases, Dr. Geoghegan was enabled, he said, to exhibit the stomachs on the table. He regretted, however, he could do little more than explain the post-mortem appearances, as in two of the cases the symptoms were not observed. After detailing minutely the morbid appearances, Dr. Geoghegan made the following summary of the conditions usually observed in the recorded cases of poisoning by oxalic acid, as well as in those just detailed by himself. 1st. Contents of the colour of coffee-grounds, consisting of altered insoluble hæma-

tosine and mucus, and separating into a supernatant fluid and insoluble deposit. 2nd. Softening of mucous membrane, with various shades of brown coloration, erosions and gelatinisation. 3rd. Brownish black ramiform vascularity of subcutaneous tissue, owing to the imbibition of the acid contents.

The co-existence in similar cases of the latter condition with the state of contents just described, is, Dr. Geoghegan observed, most important to note, as the ramiform vascularity, or even diffuse brown discoloration, may, and does, present itself in many instances as the result of the action of the lactic acid of the gastric juice only. The fatal results in cases of poisoning by oxalic acid cannot, he remarked, be referred to the corrosion of the stomach as its chief cause, but rather to the contemporaneous and energetic action which it exerts in arresting the circulatory forces. It was much to be regretted, Dr. Geoghegan observed, that the other parts of the body, the blood, &c., were not examined in the above cases. No perforation was observed in any of them, though in one the contents, including a rather large amount of acid, remained in contact with the coats of the organ; the solvent energies being, however, diffused over a large surface.

The dose was not ascertained in any of the cases. The quantity of poison found in the contents—an inquiry constantly and ignorantly made by counsel, &c.—was in one case from three to four grains, but in the two others much larger in amount, especially in the third.

In detailing the tests of the presence of this poison, Dr. Geoghegan drew attention to the deutoxide of lead or minium, the peroxide of manganese, and the chloride of gold, as *supplementary* reagents frequently furnishing useful indications.

German physicians in public practice are, he observed, in the habit of using the two former, whose mode of action is referrible to the peculiar adjustment of carbon and oxygen in anhydrous oxalic acid, which, latter may, in relation to the present subject be viewed as constituted of one atom of carbonic acid, and one of carbonic oxide the latter of which is resolved into (escaping) carbonic acid, at the expense of the above mentioned oxides. The chloride of gold is rapidly reduced by a warm solution of the poison. The two former tests are probably characteristic, the latter only confirmatory.

From its less readily associating the organic matters present; Dr. Geoghegan prefers the employment of chloride of calcium, in order to eliminate oxalic acid in the form of oxalate of lime; for the acetate of lead generally resorted to carries down much of the modified gelatine, of which the mucous membrane is constituted, and which is held largely in solution in the acid stomachic contents; hence, on the liberation of the acid such gelatine again passes into solution, and vitiates the ultimate results. When a salt of lead is chosen for the elimination of the acid, Dr. Geoghegan deems it prudent to separate previously as much of the gelatine as possible by a solution of tannic acid; Dr. Geoghegan having found that attempting to remove the acid from its organic contamination by means of alcohol, as recommended by Orfila, is quite impracticable, the animal matters retaining almost the entire of the poison.

When about to test a solution with a salt of lime, Dr. Geoghegan has long been in the habit of adding a portion of the suspected fluid to a saturated solution of the *sulphate*, in preference to the more soluble salts, from its obviating objections arising from the presence of sulphates, citrates, and tartrates. An useful character, he adds, in recognising the oxalate of lime is its solubility in strong acetic acid.

In obtaining an oxalate of lime by means of chloride of calcium, Dr. Geoghegan considers the addition of ammonia inexpedient, as it is liable to throw down organic matter, and superfluous as the liberated hydrochloric acid if the solution be moderately dilute does not dissolve any appreciable amount of the oxalate of lime. The oxalate of lime, when obtained, is to be decomposed by a solution of bicarbonate of potass, with the usual precautions. Dr. Geoghegan concluded with a detail of the various results obtained from an investigation of the contents of the stomach in the first case by the several reagents.

PATHOLOGICAL SOCIETY OF DUBLIN.

Meeting of Feb. 28th, 1846.

Dr. Law in the Chair.

Dr. Corrigan detailed to the Society the particulars of the following case of perforation of the lung and pulmonary pleura:—

John Burke, aged twenty-three, was admitted to the Whitworth Hospital on the 20th instant. He had been subject for twelve months past to cough, with some difficulty of breathing, but was not obliged to discontinue his occupation, as a servant, until about a month previous to admission, at which time the cough became more troublesome, and the breathing more oppressed, on which account he sought admission. Slight dulness, together with mucous râle were detected under the right clavicle, signs which were sufficiently explained by the subsequent discovery of red solidification and some tubercular deposition in the apex of the right lung. In the left lung the signs of phthisis were also evident, but the points of interest connected with the case were these:—In four days after admission he first complained of a darting pain in the left side of the chest. On the 25th, while the patient was sitting on the night-chair, dyspnœa instantaneously became intensely urgent; the countenance indicated great obstruction to respiration; the skin grew cold; and he panted laboriously for breath. On removing him to bed and examining the chest, the whole of its left side sounded clear on percussion, and the heart was found not only to have moved towards the right side, but was felt pulsating strongly between the fifth and sixth right ribs. Succussion indicated the presence of fluid and air in the left side, but no bourdonnement amphorique, or metallic resonance, was perceptible when he spoke, nor ringing sound when he coughed. Thus there was well marked evidence of a large quantity of air and of some fluid in the chest, but the signs which indicate a free transit of air, or *permanently* open canal between the large bronchial tubes and the cavity of the pleura, were absent—viz., bourdonnement amphorique, which is produced by the free blowing backward and forward of air through the fistulous opening, and metallic resonance of voice and cough produced by the same. The man died in the evening of this day, and on making an examination, the left side of the chest, when opened into, gave exit to a gush of air, and the heart was found in the position at which it had been felt to pulsate during life. The right lung did not present much appearance of disease, but had at its upper portion tubercular depositions in two or three places. At the posterior and lower part of the upper lobe of the left lung, a small, nearly circular, opening of about two lines in diameter was found, surrounding which was a deposition of recent false membrane. The circular orifice of the pleura communicated with a tubercular cavity of the size of a pigeon's egg, the wall of which, next the cavity of the pleura, was soft, flexible, and thin, and capable of lying down on the opposite wall, and closing the orifice of the bronchial tube opening into it, just as the pliable valve of an air pump would lie down upon and close the opening covered by it.

The cause of death, and the power of affording relief in such cases as the present, were the points to which Dr. Corrigan was anxious to direct attention. His view of the case was, that on the rupture of the pleura occurring, a rush of air into the cavity of the pleura at once followed, and that by each successive effort of the patient to inspire and relieve himself, fresh additions were, for some time, made to the quantity of air admitted, until the cavity of the pleura was filled and distended. That from the flap-like opening of the tubercular covering, none could get back again through the cavity into the bronchial tubes, and that thus confined, condensed air became a distending power, suddenly forcing the heart over to the right side of the chest, and suddenly compressing the right lung, thus producing the suffocation, which soon terminated fatally. Dr. Corrigan was of opinion that such a case can be diagnosed by the concurrence of the signs which indicate pneumo-thorax, as in this case—viz., sudden dyspnœa, tympanitic sound on percussion, immediate displacement of the heart to the right side (when the attack is in the left), and succussion, with the absence at the same time of the signs which are owing to a free passage of air through the fistulous communications—viz., bourdonnement amphorique, and metallic resonance of cough and voice; hence in such a case again occurring, Dr. Corrigan would recommend the passing a small trochar through one of the intercostal spaces to give exit to the compressing air, which the flap-like covering of the tubercular cavity prevents from escaping, and the exit of which compressing air through the canula would relieve the opposite lung and obviate suffocation, just as removing the same amount of fluid from the cavity of the pleura would give relief in pleuritic effusion and pneumo-thorax. It would not, of course, cure the disease, but it would prolong life and diminish suffering, and many have lived with pneumo-thorax for a great number of years.

Cancer of the Abdomen and Genital Organs; Cancer of the Breast; Cancer of the Uterus and Bladder; Transition of Cancerous Disease.

Dr. O'Ferrall presented two or three specimens of malignant disease, which he considered interesting, as presenting some few peculiarities. In the first case, a woman, aged fifty, of well-marked cancerous aspect, was admitted to St. Vincent's Hospital for a cancerous tumour of the left labium, there being also a large cancerous mass in the right groin. The tumour of the labium was in the ulcerated stage, and exceedingly hard; that in the groin was of a softer consistence, exemplifying the disease termed encephaloid. There was no evidence of visceral disease. The woman was in a sinking condition, worn out by great pain and diarrhœa, for the relief of which palliatives were administered during three months, at the end of which time she sunk under the frequent recurrence of the diarrhœa. During this period, too, the tumour in the groin sloughed, leaving an enormous cavity. A cast of the recently made dissection, which had been taken after death by Mr. Butcher, was exhibited. It was impossible to make another examination of the abdominal viscera while the patient lived. The only attempt made at examination was upon the patient's admission, and, with respect to the viscera, he would observe, subsequent examinations discovered no trace of any tumour connected with them. The tumour of the labium, which he now exhibited, displayed a series of cancerous masses, hard, firm, and gristly to the touch, leaving no doubt whatever as to their cancerous nature. That of the groin, as he had before remarked, was of a softer consistence, the cavity remaining being like that which is seen after the sloughing of fungoid tumours. The next point—one to which he wished particularly to draw the attention of the Society—was that, upon throwing up the abdominal flaps, a tumour was discovered, lying in the sheath of the rectus muscle, presenting the distinct characteristics of encephaloid disease, and separated from the intestines only by the peritoneum. The tumour, he observed, must have been developed during the three months that followed the patient's admission to the hospital, for, had it existed when she came in, it could hardly have escaped detection. It was obvious, then, he said, that in the same case were displayed three modifications of malignant disease—one of scirrhus of the labium, the next of a mixed character in the groin, and the third a well-marked specimen of medullary disease in the sheath of the rectus. The lungs and liver were entirely free from any abnormal deposit; they presented, in fact, no trace of disease, and the escape of these important organs after the lengthened persistence of the discharging mass, he looked on as a fact of much interest—as showing that we are not to suppose a case of malignant disease *necessarily* accompanied with contamination of the intestines or lymphatic system. From this it would appear, then, that we are not to be deterred from removing these external tumours through fear of internal organs being involved, since it is seen that in this instance the disease ran its whole course, leaving the lungs, liver, &c., entirely exempt. The case possessed, he thought, another point of interest also, viz., the existence of true scirrhus and of encephaloid disease in the vicinity of each other, a fact which must set at rest the question (if there be any one who still entertains a doubt on the subject) of the essential identity of these two varieties of malignant disease.

Dr. O'Ferral here exhibited several drawings illustrative of this statement, one in which true encephaloid disease sprung up in the cicatrix remaining after extirpation of a female breast; another still more remarkable, in which a large cancerous tumour of the vagina and uterus, encroaching on the bladder, presented at one end true scirrhous characters, while at the other it was of a genuine fungoid nature. Thus there were before the society three specimens of the concurrence of all the varieties of malignant disease in the same subject: co-existing in the first case, consecutive in a second, and continuous in the same tumour in a third. For these reasons he thought the specimens would be interesting to the society.

MISCELLANEOUS CORRESPONDENCE.

GENERAL MEDICAL ANNUITY FUND.

[To the Editor of the Medical Times.]

SIR,—Since the publication of your very excellent remarks on the principles of the "General Medical Annuity Fund," and the honour you conferred upon me by inserting my letter in your very valuable periodical, I have been favoured with several letters from gentlemen who appear anxious to learn more upon the subject, and to possess a full understanding of its character, probable advantages, and bearings in a legal point of view.

If I am not trespassing too much upon your space, or infringing too much upon your good nature, I would take the liberty of answering these inquiries in the pages of the *Medical Times*, since I shall thereby accomplish a double purpose—inform my correspondents, and enlighten others who may, perhaps, be equally desirous of information, although they have not made direct application.

The many painful facts which have been presented to me during a somewhat lengthened professional life, the awful instances of distress from sudden bereavement, and the melancholy evils resulting to widows and orphans, of destitution and, oftentimes, of moral degradation, which a small permanent provision would have obviated, have seriously impressed my mind with the necessity of urging upon the profession, that it is a duty incumbent upon us to adopt some measures calculated to meet and overcome calamities so singularly distressing to every generous and benevolent mind.

The "benevolent fund" attached to the Provincial Medical and Surgical Association is peculiarly calculated to meet temporary difficulties, and perhaps if it could be carried out in the whole of its beautiful design, there might be no necessity for another institution as far as the provincial practitioners or its own members are concerned; for the spirit of its principles is more decidedly philanthropic than my own, inasmuch as it grants assistance to those who have never contributed to its funds. But the fact that it is purely charitable seemed to me one cause of paucity in its support, as the contributors do not indentify themselves as probable recipients of its bounty.

It is nevertheless a noble institution, and recommends itself especially to the support of all benevolent persons, for there necessarily will be cases which would lack assistance without its aid, and as its contributions are small, methinks that no member of that association should withhold his mite from it, or hesitate to give it unequivocal support. The Norfolk, Surrey, Kent, Yorkshire and other institutions of an analogous character speak volumes of praise to those individuals who have nobly sustained them, and distributed their funds to meet the casualties of disease and death. But while I give these societies my warmest approval, and bid them at the bottom of my heart "God speed," I cannot but think we require an institution on other principles than those which are of a purely *charitable nature*. The "General Medical Annuity Fund" combines co-operation, and consequently personal advantages; it intends permanent, not temporary relief; and contributes aid from year to year, so long as the parties receiving need it. In its character it is not much unlike the friendly societies, for all who contribute have legitimate claims, if circumstances impel them to make those claims; nor is the possession of some private property a bar to their eligibility, as they may not have sufficient for their due maintenance and support; and consequently are entitled to make known their wants, and claim assistance, which will not be withheld, if on a fair investigation their necessities are proved. It is true, to obtain this they will be subjected to inquiry, confidential, but strict, nor will any of the recipients of this fund be known publicly, but simply by their initials; therefore, the sting of the inquiry is removed, nor will the proudest mind be wounded by this proceeding, for after all they are but reaping the fruits of their own prudence; still it is essential they should be thus subjected, for it never could be supposed, either from the nature of the institution, or from the amount of the subscription, that every member could be a recipient, or that they could at once put in a *legal claim* as they might do for a life insurance, where the contributions are proportioned to the risk.

The high character and professional standing of the directors must be taken as a guarantee that the funds of the institution will be properly and judiciously appropriated. The permanent officers (with the exception of myself, whose office can be scarcely called one of trust only, as far as the advocacy and arrangement of the principles of the institution are concerned) are well known to the profession, and to speak of their merits would indeed be a work of supererogation, but the elective officers are to be appointed yearly at the annual meeting of the Provincial Medical and Surgical Association, and will doubtless be gentlemen as well known for their probity and high standing in the profession, as those whose office is permanent. The present list of elective directors may be regarded as a pledge for future character and professional importance.

Honorary local secretaries will be appointed for distant districts, and my hope is they will be scattered over the land freely, and by their energy and perseverance advance the interest of this, to me, dearly cherished project.

Respecting its recognised legal character, I presume that when its rules and regulations are finally adjusted, when it has indeed become as perfect in all its developments as human ingenuity and provident foresight can make it, it will be necessary to enrol it in the ordinary manner of friendly societies.

Five years for the gradual accumulation of capital must be regarded as a *sine quâ non*; for five years membership before participating of benefit is not only necessary, as regards the possession of a permanent fund, but as a security against imposition. thus: a person declining in health might remit five guineas as the whole amount of what he would be required to pay in the five years, and presume that if he died in a few months from that remittance his family would be eligible for an annuity. But common sense will tell any one that to grant an annuity under such circumstances would be to hold out a premium for neglect, and to neutralise the test of time demanded by every friendly institution, as a security against fraudulent and unfair membership.

It has been suggested also by many of my correspondents, some of whom have a very high place in my esteem, that persons advanced in life should be required to pay a larger sum than young members, as entrance fees, on the ground that their families might be fairly expected to fall early on the funds; and this would be a correct view of the case, and in accordance with the usages of other societies, were we to recognise every member as liable to become chargeable; but this institution combines philanthropy with co-operation, and the probability is that the great majority of contributors will not be recipients. Aged and wealthy gentlemen would doubtless object to pay entrance fees, but would freely part with their annual guinea, and give to us the sanction of their names; thus by demanding entrance fees we should lose all advantage to be derived from them, and I fear, in the end, receive but a poor equivalent for the loss.

One other subject is essential to be known; the five years necessary membership commenced from the Sheffield meeting, in July 1845. Gentlemen, therefore, who do not wish to lose a year, must pay their subscriptions before the 30th of June, 1846, when the books will be made up, and the whole business put into a train for the meeting of the directors at Norwich, where the Provincial Medical and Surgical Association will be held this year.

Dr. Percival, speaking of the local charitable institutions which were in existence in his day, has the following striking passage, which, I trust, your readers will pardon me for quoting.

"One comprehensive establishment seems to be more eligible than many on a smaller scale; for it would be conducted with superior dignity, regularity, and efficiency, with considerable saving in the aggregate of time, trouble, and expense, with more accuracy in calculations, relative to its funds, and, consequently with the utmost practicable extension of its dividends."*

In a monthly miscellany published at Oxford in 1750, entitled the *Student*, is detailed "a scheme to raise a fund for the maintenance of the widows and children of the inferior clergy." I could fancy that from this small beginning have emanated the different institutions now in operation for the widows and orphans of the clergy. The person who suggested the "scheme" was not a clergyman, but he advocated the cause with much zeal and ability; one passage I will quote as a spur to our own endeavours.

"We may observe how the men of trade unite themselves into societies, and contribute a certain sum weekly, or monthly, to make up a purse for the benefit of the whole. When any man is sick, he is allowed so much per week out of this fund till he can perform his business; and if any man die, his widow receives some handsome present from the common stock to comfort her for her loss. These are things done by the lowest rank of mechanics; and surely men of liberal education must have more extensive benevolence and generosity than the illiterate." If this reproach was sufficient to stir up the active benevolence of the clergy of that day to noble exertions, let the spirit of the dead which lives in this passage speak to the hearts of the living of our profession, and with love and energy in our souls, let us "go and do likewise."

In conclusion I trust the kind and generous appeal which you have made to the medical public, embodying facts, the result of your own experience—facts I fear which might be multiplied, by the experience of others, for such facts have come with fearful force upon my own mind—will not be lost; but that its very truthfulness may excite desire to remedy the evil. The officers of this institution are earnestly bent upon the establishment of a permanent good in the profession, they will abate nothing in their zeal and benevolence in furthering the object they have in view, but they ask for co-operation, they ask for the united zeal and energy of the whole profession, for without it their efforts are useless, but with it the final accomplishment of the project cannot even be problematical. The late political movement in the profession is a powerful evidence of what may be done when once our great energies are put in motion—if a corresponding movement could be excited on the behalf of benevolence how great would be the result! Surely the cause is sacred and worthy our best consideration, for be it remembered that God will strengthen the hand which sustains the widow and the fatherless, and bless the heart which yields them consolation in the hour of tribulation and misery.

Again thanking you for the helping hand so kindly and generously bestowed,

Allow me to remain, Sir,

Your obedient servant,

EDWARD DANIELL.

Newport Pagnell, Bucks, April 11, 1846.

P.S.—Several gentlemen having applied for rules, &c. Allow me to inform them that between 2000 and 3000 have already been distributed and the remaining copies are few; but the rules will be found as an appendix to my "Address."

* Vide Percival's Medical Ethics, ed. 1827, p 360.

The mortality in the hospitals at Oran is at present very great; during the last three months of the past year, more than a thousand deaths have occurred in the province of Oran alone.

SHAM ASSOCIATIONS.

Sir,—A meeting—so numerous that the attendants are said to have all gone home in *one* cab—was held at the Freemason's Tavern, on Saturday evening, of what is somewhat impudently called a "*Committee* of *Associated* Surgeons," the fact being that there is, and has been, no such *Association*, and that the thing called a Committee has had nothing entrusted or committed to it by any party or persons. It is, in short, a non-commissioned committee of an association *in nubibus*—the conjured-up ghost with which two or three politicians, out at elbows, hope to fight the solid reality of the National Association. A flaming report of the proceedings was foisted on some of the morning journals of Monday, in which speeches, and questions, and answers were attributed to a Mr. Bottomley, of Croydon; to a Mr. Lewis, of some place unmentioned; to a Mr. Jones, of Portland-street; to Mr. T. Wakley, the coroner; and to Mr. Yearsley, the tonsillatist. A Mr. Blixam's name is also mentioned, with a Mr. Ottley, thus completing the court circular of the aforesaid cab-load. Mr. Yearsley possesses a name not unadvertised. Mr. Wakley is as well known as he probably wishes to be. Mr. Bottomley, I surmise—it is a mere guess—is a person of considerable weight. Mr. Lewis, luckier than his compeers, has never before, we believe, been heard of; but as for Mr. Blixam and Mr. Jones, of Portland street, we are just thus far informed, that the *Medical Directory* does not include in the list of legitimate practitioners their, no doubt, very honourable names.

Is this kind of "humbug"—I know no better term—to go on for ever? Pray interpose, or you may again hear from

Public Decency.

GOSSIP OF THE WEEK.

Concealment of Birth in Bavaria.—According to the criminal code of Bavaria, concealment of pregnancy and delivery is not punishable, unless such concealment cause the injury or death of the child, or be intended as a preparation for its murder. This enactment, however humane it appears at first sight, is most injurious to morals, for it greatly conduces to the procuring of abortion, and infanticide. Dr. Gaderman denies the assertion in a criminal code that "infanticide would be occasioned by punishing concealment of pregnancy or delivery simply; he points out that the criminal code pays too little regard to the circumstance, that the investigation into concealment of pregnancy or delivery is among the most difficult, uncertain, and doubtful, in legal medicine, and that, on account of these circumstances, the accused frequently escape, and the difficulty is much increased when it is necessary to prove, if the child is born dead, that its death was a consequence of the concealment of pregnancy, or, where it is born alive, that its subsequent death was a consequence of the concealment of delivery.

New Lunatic Asylums.—At the last meeting of the county magistrates at Preston, it was proposed in consequence of the large number of pauper lunatics within the county, that two lunatic asylums be established, the one to be situated in Salford Hundred, and the other in the Hundred of West Derby. It appears that not one half the pauper lunatics of the county are domiciled in the present asylum near Lancaster, only 658 out of about 1400, being properly located, the remainder are dispersed in the various workhouses, or buildings connected with them, to the serious inconvenience of the sick poor, who are obliged to submit to the shouting and screaming of their less fortunate brethren.

A civil hospital is about to be built at Constantinople, at the expense of the dowager sultana. It will be afterwards supported by the government.

Blood-Corpuscles.—At the last meeting of the Zoological Society a communication was read by Mr. Gulliver, from Dr. Davy, on the blood-corpuscles of the humming bird; this talented microscopist took occasion to remark that they were, as he expected, the smallest yet described among birds. Referring to his elaborate tables of his collected measurements of the blood-corpuscles of vertebrata, published in the proceedings of the Zoological Society of London, October 14, 1845, Mr. Gulliver observed that, although there is no connection between the size of the blood-corpuscles and that of the animal in mammalia of different orders, there is such a connection in the same natural family, as in the *Ruminants* and *Rodents*; that is to say, the largest species of one family have regularly larger blood corpuscles than the smallest species of that family. Now, he shows that the law for the size of the blood-corpuscles is the same in the entire class of birds as in a single family of mamals; for his copious tables of measurements contain no example of large blood-corpuscles in the smallest birds, or of comparatively minute corpuscles in the largest birds. Mr. Gulliver also read a paper at a former meeting of this Society on the spermatozoa, having availed himself of the opportunity afforded by the sudden death of the large Polar bear at the Zoological Gardens, Regent's Park, on which occasion he examined the spermatozoa of that animal, and observed that they resembled in all respects the spermatozoa of numerous other mamalia, and have none of those special marks of organisation described and figured as the spermatozoa of the bear by Professor Valentin. Hence, notwithstanding Valentin's observations, Mr. Gulliver remarked, that it is still a question whether the spermatozoa be independent beings or merely free and floating cilia.

Samuel Devenish, Esq., the senior surgeon to the Honiton Dispensary, has recently been elected surgeon to the first division of the Union.

Obituary.—At Lasswade, 25th ultimo, George Ledingham, M.D., assistant-surgeon, 87th Fusiliers. On his passage to England, in the Apollo, Mr. William Chartras, late surgeon of H. M. surveying-vessel, Philomel. April 5th, at Knock Boyne, Luke Byron, M.D., surgeon of the county of Meath Infirmary.

Appointments.—Assistant-surgeons: J. Reid, from the Museum at Haslar, to the Rodney, vice Whitmarsh, promoted; J. Findley to the Excellent.

War-Office, April 14th.—3rd Dragoon Guards: Assistant-surgeon Henry Mapleton, M. D., from 40th Foot, to be assistant-surgeon, vice Tufnell, appointed to the Staff. 56th Foot: Assistant-surgeon Thomas D'Arcey, from the 85th Foot, to be assist.-surgeon, vice Campbell, promoted. 87th Foot: Assistant-surgeon Henry Clinton Martin, from the Staff, to be assistant-surgeon, vice Ledingham, deceased. 65th Foot: Assistant-surgeon Robert Keating Prendergast, from the 90th Foot, to be surgeon, vice Marshall, appointed to the 84th Foot. 70th Foot: Assistant-surgeon Henry Pilleau, from the Staff, to be surgeon, vice Mabarg,, deceased.

MORTALITY TABLE,

For the week ending April 11, 1846.

Causes of Death.	Total.	Average of 5 summers	Average of 5 years
All Causes . . .	861	892	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	144	162	188
Sporadic Diseases—			
Dropsy, Cancer, and other Diseases of uncertain or variable Seat . . .	85	98	104
Diseases of the Brain, Spinal Marrow, Nerves, & Senses	159	155	157
Diseases of the Lungs, and of the other Organs of Respiration	270	271	294
Diseases of the Heart and Blood-vessels . . .	37	26	27
Diseases of the Stomach, Liver, and other Organs of Digestion . . .	70	65	72

No. 343. **SUMMARY.** April 25.

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

[From our own Correspondent.]

ACADEMY OF SCIENCES.

Meeting of the 13th April, 1846; M. Mathieu in the Chair.

Formation of Organic Tissues.—M. Payen has long since shown that the chief component of vegetable matter, cellulose, is chemically identical with starch, gum, and sugar, is convertible into each of these substances, and differs from them only by its atomic disposition, and by the property it enjoys of assuming the cellular shape. Lichens, containing cellulose in a weakly organised condition, yield under the action of boiling water nutritious jellies; but when the organisation of the elementary principle is more advanced, as it is, for instance, in the textile fibres of cotton, flax, and hemp, it resists energetically the solvent powers of the digestive apparatus. Cellulose is a ternary substance, composed of oxygen, hydrogen, and carbon; nitrogen in plants pre-exists to the formation of cells, in the extremely thin walls of which it is merely incarcerated. The deposition of ligneous matter takes place only with the progress of age, and constitutes by its abundance the differences between hard and soft woods. It had been hitherto supposed that animal textures differed from vegetable tissues, particularly by the presence of nitrogen in a state of combination; and that animal membranes were quaternary substances. M. Schmidt, in the first place, MM. Kœlliker and Lœwig, after him, have demonstrated that in one class of mollusca (mollusques tuniciers), the general envelope of the animal is essentially formed of cellulose, identical with the same substance in the vegetable kingdom; both are acted upon in the same manner by sulphuric acid, being first changed into a substance which iodine colours blue, and being both transformed into dextrine by a prolonged action of the acid. In their state of integrity, the envelopes of the above mentioned mollusca contain twenty-seven per cent. of nitrogen, which acids and potash easily remove, leaving only three per cent.—a circumstance to which is due the interesting discovery of the identity of nature of vegetable and animal cellulose.

The Baron Liebig *versus* Messrs. Gerhardt and Laurent.—Professor Liebig, having carried sulphocyanogen to a red heat, found that this substance was decomposed, and gave birth to sulphur, sulphuret of carbon, and a lemon-coloured powder, insoluble in water and alcohol, and yielding at a white heat three volumes of cyanogen and one of nitrogen. With this powder, potassium combined with a strong disengagement of light, and hydrogen formed with it a compound analogous by its properties to hydrocyanic acid. The newly discovered body Professor Liebig called "mellon," and represented it by $C^6 N^8$. The constitution of mellon, as announced by the illustrious dean, was soon contested by M. Voelkel, in a treatise on the compounds of sulphocyanogen, and Professor Gerhardt also questioned the results of Baron Liebig's experiments. The latter resumed his researches on the subject, and persisted in his original statements, pointing out the mellonuret of mercury as furnishing perfectly pure mellon by distillation. In a first paper, Messrs. Laurent and Gerhardt endeavoured to establish that the mellon was nothing else than an acid, and that Baron Liebig's mellonurets were real salts. Baron Liebig, in an answer, inserted in the *Revue Scientifique*, charged the experiments of the French chemists with inaccuracy, and they instantly forwarded to the Institute a complete refutation of Baron Liebig's ideas on the compounds of mellon and sulphocyanogen. In their opinions, mellon should no longer be represented by $C^6 N^8$, but by $C^6 H^3 N^9$; it does not combine with potassium, but forms with it a salt with a double basis, $C^6 N^8 M^2$, with a disengagement of ammonia. As a consequence of their researches, Messrs. Laurent and Gerhardt stated that M. Liebig's sulphocyanogen contained hydrogen—that the *melane* was only a mixture of mellon and polyene—that the *formula* of the *chlorocyanamide* was erroneous—and that the decomposition of the latter substance by heat, besides mellon and muriate of ammonia, gave one equivalent of *muriatic acid*; and, therefore, that Baron Liebig's theory of mellonic compounds was fundamentally wrong. Such is the origin of the chemical debate still pending before the Institute of France—a debate in which both parties have hitherto displayed far more talent than temper, and have allowed themselves to be carried by the energy of their convictions beyond the usual limits assigned to scientific discussion.

Spontaneous Hydrophobia—Rabies in Herbivorous Animals.—Dr. Gurzon, chief surgeon of the African army, states that during the month of January a veterinary surgeon died in Algiers of spontaneous hydrophobia. Dr. Gurzon's communication containing no details as to the origin, symptoms, progress, and post-mortem examination of the case, it becomes quite impossible to draw from it any conclusions of a practical nature; and we must still remain in doubt, whether, in this instance, as in many others, the horror of liquids and of shining bodies was merely symptomatic of acute cerebral disorder, or of that special disease which results from the bite of a rabid animal. We may also notice another part of Dr. Gurzon's letter, wherein it is stated, that although herbivorous animals do not become spontaneously rabid, still rabies can be communicated to them by a bite. He reports two instances of horses who, having been bit by mad dogs, became affected with hydrophobia; in one of the horses incubation of the disease lasted sixty days, and the animal wounded a man and a horse, on whom no symptoms have hitherto appeared.

ACADEMY OF MEDICINE

Meeting of April 14th, 1846; Dr. Roche in the Chair.

The Plague.—M. Rochoux inquired why the discussion on the quarantine question was not resumed? M. Prus regretted it had not been in the power of the commission to meet during the preceding week, and consequently a further delay was still necessary.

Presence of Salts of Copper and Lead in Distilled Waters.—M. Guibourt read a report on a communication by M. Brifault, relative to the presence of mineral poisons in distilled waters—orange flower water, for instance. According to the author of the communication, the noxious substances contained in the distilled waters are due to the nature and condition of the vases in which they are preserved. M. Guibourt proposed that the thanks of the Academy be forwarded to M. Brifault, and that a letter be addressed to the minister of agriculture and commerce on the subject, requesting him to enforce the use of glass vases, or at least to fix the standard of the tin to be employed on all domestic purposes, and recommending that five per cent. of alloy at most be tolerated. M. Chevalier: Copper and leaden vases may certainly become the cause of serious alteration of the contained fluids; but other vases are in common use which I think more dangerous still—zinc vessels not only are used for distilled waters, but are almost exclusively employed in the south of France to receive oils, by which they are speedily attacked, the contained oil becoming a powerful emetic; it would, therefore, be necessary to proscribe zinc as well as copper and leaden vases. The report was unanimously adopted, with Professor Chevalier's suggestion.

ANATOMICAL SOCIETY.

Meeting of April 17th, 1846; Professor Cruveilhier in the Chair.

M. Pigné read a report on a case of stricture of the cœcum, with dilatation and hypertrophy of the small intestine, and atrophy of the colon. The following is an abstract of the report, which was unanimously adopted by the Society:—The point towards which the reporter directed chiefly the attention of the meeting, was the hypertrophous condition of the small intestines. It is a law which has been long since demonstrated, that an increase of size is always produced by an increase of the functions of any organ. Morgagni had already said, "Quia crebriores et validiores motus, major musculorum crassitudo sequitur"—a proposition which is susceptible of receiving numerous illustrations, and is not less true when applied to organs of nutrition than to those of relation. A physical obstacle of any kind to the progress of the blood through the origin and arch of the aorta, produces as an immediate consequence an increase in the action of the heart, proportionate to the obstacle to be overcome; and this increase of activity very soon brings on a thickening of the walls of the left cavities of the viscus. The right side of the heart we find hypertrophied by an obstacle to the circulation of the venous blood in the pulmonary artery or in the lung. A hernia—a stricture of the intestine—a tumour compressing its walls—will cause an arrest in the progress of fœcal matter through its cavities. A dilatation above the stricture forms, and the intestinal parietes, contracting with more than their accustomed energy, become soon hypertrophied. The same remarks may be applied to the state of the urinary bladder and urethra, behind a stricture of the passage. Let the neck of the womb be obliterated; the catamenial secretion must accumulate in the cavity of the organ, the walls of which will, in a short time, be thickened, in consequence of its efforts to get rid of the accidental deposit. Hypertrophy of an organ results, therefore, in many instances, from an increase in its functional activity, and it is for that reason M. Pigné calls it functional hypertrophy, in contradistinction to nutritive hypertrophy, the cause of which is different. We meet with this same functional hypertrophy in all other organs. Thus, suppose one kidney destroyed by disease, the other kidney is obliged to perform double duty, and speedily increases in size. By mercurial salivation, the secretion of saliva is much more abundant than during health, and we find the glands also enlarged. When one lung is incapacitated by any cause from accomplishing its important function, the healthy lung is observed to breathe with greater frequency and energy than during health, and the increase of its size is proved by the depressions left on its surface by contact with the internal face of the ribs. Women who suckle only from one breast, offer an hypertrophy of the mamma which has been called into action

and a comparative atrophy of the other. In the case which occasions the present report, the end of the small intestine was considerably hypertrophied, in consequence of a stricture of the cœcum. Let us, therefore, examine the question of hypertrophy in organs of excretion. The hypertrophy of excretory organs is always proportioned to the intensity of the obstacle to be overcome, and to the strength of the patient. It is also more considerable when the obstacle has been of long duration than when it is recent; dilatation of the cavity only takes place when its walls have, by the gradual accumulation of their contents, lost their elasticity; the parietes then become thinner at the expense of their first increase in thickness. Another series of anatomical alterations is also observed: the ducts through which the arrested fluids were to pass, become obliterated, and the accumulated matter above the obstacle rises gradually until it causes compression of the elaborating viscus itself, in which it at last develops morbid action; this is often observed in the kidneys, and some apoplectic congestions of the lungs acknowledge no other cause; hence, also, œdema and serous effusions from impeded venous circulation. Excessive distension terminates in one of three modes—1, Rupture; 2, Inflammation and ulceration; 3, Hernia of the mucous membrane through the muscular fibres, fresh distension, and ultimate rupture of these newly-formed appendices. The history of hypertrophy in organs of excretion presents, therefore, two distinct periods: in the first, the walls are thickened and the cavity slightly enlarged or diminished; in the second, there is dilatation of the cavity and increase of thinness of the walls.

HOSPITAL NECKER.

April 17th.

CLINICAL LECTURE. *Diseases of Infants;* By PROFESSOR TROUSSEAU.

Sclerema.—The nature of this disease has been the text of much difference of opinion. M. Valleix looks upon it as a form of œdema; others consider it as a sort of inflammatory state of the subcutaneous cellular tissue. It has also been compared to what Vogel calls in animals, "febris roborosa"—a disease of a spasmodic nature, in which the soft parts acquire a degree of solidity graphically compared to the hardness of *oak;* this was in some measure the opinion entertained by Dugés relative to this disease; but we think the word spasmodic is misapplied, when used in reference to textures which are not muscular. Sclerema has been also attributed to patency of the foramen ovale, to pulmonary œdema, to pneumonia, to incomplete development of the organs of respiration, and, lastly, to cutaneous or hepatic affections. It is probable that many maladies have been confounded under this one comprehensive appellation, "induration of the cellular tissue," and this would account, in a satifactory manner, for the numerous physical conditions to which sclerema has been referred. You have seen that pressure of the skin did not cause pitting, as in cases of œdema; and that, on dividing the skin after death, not a drop of fluid escaped from the cellular tissue. We cannot, therefore, consider the malady as identical with œdema. The statistics of the Foundling Hospital in Paris show that of 300 cases of sclerema, 200 have proved fatal. The coldest months of the year are also those during which the complaint is observed with greatest frequency. The influence of cold on the production of this malady is a demonstrated fact, as it is in the anasarca which sometimes follows scarlatina. Indeed, we may look upon the physical condition of the body after scarlatina, as resembling closely that of a newly-born child. Its vascularity and desquamation increase its natural susceptibility to atmospheric mutations.

Meningitis—Macula Meningitica.—We will now turn to the consideration of some important points of the diagnosis of meningitis in children. Let us begin by narrating rapidly the cases of two little patients at present in our wards. One, aged three years, admitted on Sunday, had been previously perfectly healthy, and up to Saturday last had presented no sign whatever of illness. On Saturday evening he was suddenly attacked with convulsions, and sank into a state of stupor. Was this stupor to be referred to meningitis or to idiopathic convulsions? No spontaneous vomiting had taken place. The pressure of the finger produced, however, very readily persisting stains on the skin of the chest. Meningitis was diagnosed, and the symptoms which have since appeared fully confirm that diagnosis. The stupor has increased, and the respiration presents a characteristic sign, towards which I beg to direct, very particularly, your attention. Three and four rapid inspirations follow each other, and are immediately succeeded with six, eight, or nine seconds of absolute repose of the chest, during which the child does not breathe. This interruption of the respiration, which I have observed to last *fifty-seven seconds* in one case, occurs only in meningitis. The state of the pulse in most diseases is always in harmony with the respiration; the pulse generally being in acute disorders four times as frequent as the respiration, so that by counting the one, you may, in most instances, form an accurate estimate of the other; not so, in meningitis. In one child I counted only *three* inspirations in one minute, and yet the pulse beat 200 times. In the infant who is at present under observation, the pulse marks 214. This ataxic state of the functions in meningitis is truly remarkable. You will also notice that, although this child has taken no food for three days, still he has not fallen away.

The other child was twenty-three months old; he had been ill two months, suffering from loss of spirits, feverishness, and cough—the prodromic signs attributed by Dr. Rilliet to meningitis—but observed that the child's liver was very large, descending as low as the pubes. Diarrhœa also existed for two months, and, having ceased four days ago, the child became affected with convulsions and stupor, and next morning his arms, feet, and legs were œdematous. Is it not evident that the symptoms observed during the eight weeks which preceded admission, were those of a tubercular diathesis, and not the premonitory signs of encephalic inflammation? On Sunday, for the first time, spontaneous vomiting took place, and on Monday morning we produced the meningitic stain by pressure on the legs and arms, but we failed in obtaining it on the chest and head. The pupils were much dilated, and paralysis of the levator muscle of the eyelid existed; under the circumstances we asserted the presence of meningitis, and the child having died yesterday (Thursday), we now present to you the anatomical proof of the accuracy of our diagnosis. The membranes at the basis of the brain are thickened and opaline; tubercular granulations are present; the lungs are filled with strumous collections, and the liver is in a fatty state of degeneration. In order to test the value of the macula meningitica, we have tried to produce it in the twenty-two infants at present in our wards, under treatment for various complaints, and although we rubbed forty times the skin of those we do not suspect to be affected with meningitis, we failed in producing any thing but an *evanescent* redness—whereas one or two applications of the finger were amply sufficient to produce a *persisting* stain in the case of meningitis, in whom, besides a considerable degree of sensibility, may be noticed, contact appearing to produce in them pain, expressed by distortion of the features and a faint cry.

DAN. M'CARTHY, D.M.P.

Spain.

ANATOMICO - PATHOLOGICAL OBSERVATIONS UPON PHTHISIS.

By D. JOSÉ SECO BALDOR.

(Continued from page 5.)

CASE 3rd.—*Chronic Pleurisy; Miliary Tubercles in the Lungs; Acute Pneumonia and Bronchitis; Crepitous and Sibilous Râle.*

A man, of dark complexion, aged 29, possessing a sanguineous temperament and well-formed chest, was admitted into the Military Hospital of Lavapies, for gastric fever; from which he recovered in a few days. After a short convalescence, he complained, on the 30th of May, of cough and difficulty of respiration. Upon farther inquiry, it was found that he had suffered, at various times, from pains in the sides and other parts of the chest, and that, for three days, he had experienced cough, oppressed respiration, impaired appetite and evening-and-night fever. The expectorated matter was sanguinolent, frothy, viscid; pulse strong and frequent; skin hot and dry; face somewhat flushed; tongue moist; appetite extinct; thirst excessive. The sound of the thorax was dull in the inferior third of the right side; clear, in all other points: the respiratory murmur extinct in the inferior third of the right anterior region; perceptible and clear in the left axilla; but mingled with sibilous *râle* in the right sub-clavicular region, and in the lower third of the left side; and with crepitous *râle* in all the other regions of both sides. From these signs, might obviously be inferred the existence of acute pneumonia; resulting from exposure to the night-air. Blood-letting of twelve ounces; emollient cataplasms to the chest; rigorous abstinence; pectoral decoction, with syrup of gum (Acacia).

On the following days, the anti-phlogistic and revulsive plan was continued. After reiterated general and local abstractions of blood, two blisters were applied to the arms; and one to the breast. Yet the dyspnœa was aggravated; the cough became daily more obstinate and troublesome; expectoration more difficult and scanty; the sputa more viscid, and pulse quicker. The skin was constantly dry. The respiratory murmur receded, by degrees, from those points in which it had previously been mixed up with *râle*. The latter continued till death which took place on the morning of the 6th, preceded by a most painful struggle.

Necrotomy.—The whole surface of both lungs adherent to the contiguous parts, by bands and pseudo-membranes, thick, strong, and resembling, in their rugged aspect and reddish colour, those which are commonly met with in the inflamed pericardium. Their parenchyma obstructed by accumulated blood and serum; bleached and full of miliary tubercles, larger and more abundant in the circumference, than in the centre, of the organ. The hyperæmia did not reach the second degree, that of hepatization; for no portion of the lung sank in water. The bronchial mucous membrane, in many points, injected. The liver, stomach, and spleen, adherent to the diaphragm; but otherwise healthy.

Reflections.—In the first two cases, percussion and auscultation detected, with admirable precision, lesions which, without their aid, it would have been impossible to decide the existence of. These means of exploration were, however, not required, in the present case, to discover the inflammation of the lungs and pleura. Yet even here, they were useful; not only as confirming the indications afforded by the other symptoms, but rendering the diagnosis more precise by an exposition of the extent and degree of the pneumonic affection. In fact, the presence of the crepitous *râle* in nearly all the regions of the thorax, while indicating that both lungs were involved in almost general inflammation, shewed that the inflammatory process had not passed the first stage. Yet, with respect to the condition of the right lung, the author had been somewhat deceived: for the obtuse sound of the parietes, and the absence of the respiratory murmur in the anterior inferior part of the right side, led him to suspect hepatization of the inferior lobe, at least in its anterior portion. Both phenomena were, however, otherwise accounted for: the lung, pushed upwards by the pus, and confined by bands and pseudo-membranes, could not, when the fluid had been partly re-absorbed, recover its original volume; and the liver had occupied the vacancy consequently resulting in the pleura. The acute bronchitis, denoted by the sibilous *râle*, had left its traces in the body.

With respect to the pleurisy, there was no stethoscopic sign; but the pains in the breast sufficiently indicated its existence; and the lesions met with in the pleura, confirmed the report of the patient with regard to its long standing.

The numerous miliary tubercles disseminated through the substance of both lungs, ought not to be considered as of constitutional origin. The patient did not exhibit, either in his general health, or in the conformation of his thorax, any predisposition to phthisis. This, in fact, is one of those cases, in which the development of tubercles must be attributed to inflammation of the pleura; not only for the reasons already pointed out, but from the recent date of the tubercles compared to that of the pleurisy, and, finally, from their greater volume

and abundance in proportion to their proximity to the surface of the lungs, which had formed the seat of the chronic inflammation. The pneumonia and bronchitis were obviously too recent to have existed anteriorly to the tubercles; and, so far from having excited any influence upon their development, it is probable that the great extension which the pneumonia rapidly acquired, and its obstinate resistance to the vigorous treatment employed, resulted in part, from the pre-existence of the tubercles. The complete adhesion of the lungs to the contiguous parts, and the concealment of his relapse by the patient, with the view of escaping dietetic restrictions, perhaps contributed, also, to the unfortunate result.

CASE 4.—*Chronic Pleurisy of the Right Side; a Tubercle in the Inflamed Pleura; the Right Lung compressed, and pushed upwards, by the Liver, to the Fifth Rib: Ulcers in the small Intestine; Crude Tubercles between their Fundus and the Peritonæum: Dropsy of the Pericardium.*

A grenadier, ruddy, and of sanguine temperament, was admitted into the Hospital of Saint Isabel, with inflammation of the right pleura. From the man's statement, the affection was, at first, chronic; but had since become acute. By the employment of general blood-letting, leeches, blisters, pectoral potions and abstinence, the pain and fever were soon reduced; as also the obtuse sound emitted by the inferior half of the right side of the thorax (on percussion): and the patient became nearly convalescent. Nevertheless, the cough did not wholly subside; and, although eating well, he perceptibly lost flesh. The fever returned. The pulse became weak and very small: diarrhœa, with œdema of the lower extremities, supervened; and death, from exhaustion, on January 1st, 1837.

Necrotomy Twenty Hours after Death.—Thorax: Left pleura, and lung perfectly sound. The pulmonary and costal pleura of the right side, thickened and adherent. Right lung compressed from within, outwardly, and, from below, upwards; so that it reached only to the fifth rib. One tubercle in the right pleura; none in the lungs. About four ounces of transparent serum in the pericardium. Heart small and somewhat pallid. Left auricle small: right very large and filled with black fluid blood. *Abdomen:* Liver pale-coloured, voluminous, and reaching to the fifth rib. Jejunum and ileum exhibiting, in divers points, large ulcerations which comprehend the whole circumference of the intestine, except the portion adherent to the mesentery: between the fundus of these ulcers and the peritonæum, crude tubercles, considerably developed. Colon partially injected.

Reflections.—This patient was evidently the subject of pleurisy terminating in suppuration. The more fluid portion of the pus had been absorbed; and the liver occupied its place. The ascent of this organ, when the lung, after the absorption of the fluid contained in the right pleura, could not, in consequence of its adhesions, regain its pristine volume, is a fact of frequent occurrence, yet, hitherto unrecorded: and, no where, has the opposite case been mentioned,—that of the descent of the liver, consequent on the effusion of a large quantity of pus, or other fluid, into the right pleura. In the former case, the same ascent of this organ was observed; and there will be occasion to note its occurrence in other instances.

In the inflamed pleura, one tubercle was discovered; and divers others in the ulcerated portions of the small intestine, between the ulcers and the peritonæum. Here then, without doubt, the tuberculization was the result of the inflammatory process in the thorax and abdomen: for it would be absurd to regard a solitary tubercle of the right pleura as the cause of the pleurisy, and to overlook the connexion existing between the inflammation and the pus. With respect to the tubercles developed in the sub-peritonæal tissue, or rather between the serous and muscular membranes of the intestines, they may be reasonably attributed to the ulcerated condition of the mucous membrane. It is impossible to regard the tubercles as the cause of the latter; since, in none of them, had the process of softening commenced; and, consequently, they could not have produced ulceration. Here, then, is a fact completely hostile to the opinion of Laennec; who considers tubercles to be invariably independent on inflammation, and, in many instances, as the cause of that process and its consequences.

Lastly, it is interesting to mark the relation which existed, in this case, between the weak and almost imperceptible pulse and the small and pallid heart, compressed by an accumulation of four ounces of effused fluid.

[To be continued.]

ORIGINAL LECTURES.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

BY G. J. GUTHRIE, F.R.S., &c.

LECTURE I.

Wounds and injuries of arteries; Structure of arteries; External coat — Internal — Middle; Fourth coat of Haller and Malgaigne; Efforts of nature in healing wounds of arteries; Effects of small puncture; A large puncture; Case of puncture of the ulnar artery by a medical student in bleeding a friend; Case of a tailor of the 40th regiment after the siege of Badajos; Effects of division of a large artery to one-third or one-fourth of its circumference; Case of a wound of the carotid by an arrow; Mr. Chamberlaine's case; Case in St. George's Hospital of stab in the thigh; Effect of a transverse opening in an artery—in man, in horses, and dogs; Complete division of an artery; Insufficiency of experiments in ascertaining the processes by which hemorrhage is suppressed; Effects of complete division on arteries of small dimensions; Case of soldier whose arm was shot off at Cuidad Rodrigo; Case of soldier whose leg was carried away at Salamanca by a cannon-shot; Contraction of extremity of the wounded artery; Effect of pressure on surrounding parts on wounded arteries; Division of arteries in amputation at the hip-joint; Division of femoral high up in the thigh; Case of thigh torn off by a cannon-ball; Probable result to the artery in such a case; Case at Salamanca; Processes in a somewhat smaller artery; Hemorrhage from lower end of divided artery; Processes of nature for closing the lower end of a divided artery; Effect of the collateral circulation; Appearances in lower end of artery; Case of a serjeant of the 62nd regiment at Toulouse; Case of a soldier of the German heavy cavalry; Conclusions to be drawn from these facts.

GENTLEMEN,—In commencing our inquiries into the subject of wounds and injuries of arteries, and the treatment and operations required for their cure, I shall detain you for a moment on that of their structure. In Great Britain anatomists usually consider them as composed of three coats:—1. A strong, fibrous, interwoven, dense, unyielding, external tunic, firmer within than without, and of a greyish-white colour. It may be destroyed by pressure, but does not tear or separate under the application of a silken ligature; it is especially elastic and retractile. 2. A fibrous, contractile, or pseudo-muscular layer, of a yellowish-red colour—more developed in the smaller arteries—less coloured in the larger, with fibres—are nearly circular, and united by others said to be oblique, or spiral; they are elastic to a certain extent, and eminently retractile and contractile. 3. A serous coat composed in the aorta of several layers. In the extremities it is a smooth and polished membrane, of a whitish-yellow colour, without fibres, soft and unctuous to the touch, of a dense, although partly transparent, structure, and readily torn in every direction by a slight degree of extension. These two last coats yield to, and are readily divided by a ligature applied to the artery with a moderate degree of force.

Baron Haller, and several of the later French anatomists, particularly Malgaigne, reckon the cellular substance which may be perceived in the aorta, but not in the pulmonary artery, between the middle and internal coats, as a fourth coat. They consider this part to be the principal seat of disease in arteries, and that to it the artery owes much of its elasticity. The structure of the external and the middle coats of an artery appears to be less dense in the female and in children than in the male, and although there is so general a resemblance between the arteries of man and of animals, as to render them apparently similar, their structure is not exactly alike. A second cellular coat, for instance, is found between the external and middle tunics in the ox. It has not been practicable to cause an aneurism in dogs, and the apparent similarity of these vessels, with reference to the effects, which may result from injury or disease, cannot be depended upon; nor can any confidence be granted to the numerous experiments which have been very cruelly made on animals with the view of elucidating the various processes which occur in man.

No reliance can be placed on the efforts of nature in healing a wound in an artery in man, although it does occasionally occur. They are not to be even expected after a secondary hemorrhage, which is very rarely effectively suppressed without the assistance of art.

A *small puncture*, made with a needle, will sometimes heal, as it generally does in dogs. I have, however, seen several instances in which the femoral artery was wounded by a tenaculum during amputation, and a secondary hemorrhage followed after ulceration, requiring the application of a ligature. A *larger puncture*, or a longitudinal slit of, from one to two lines in extent, does not commonly unite, except under pressure, although the edges of the wound may not always separate, so as to allow blood to issue in any quantity. It sometimes only oozes out, and occasionally does not do even that, unless some obstacle to the circulation takes place below, when blood is propelled with a jet; and the edges of the cut having once been separated, blood continues to be thrown forth in considerable quantity. When the bleeding is suppressed by pressure made on the artery above, and all causes of obstruction are removed from below, the edges of the little wound approximate, and the circulation through the wounded artery may be, and often is carried on for several hours without further hemorrhage, when it may again recur without any obvious cause. In an artery of the size of the temporal a longitudinal slit may sometimes heal without the canal of the artery being obliterated, although this very rarely takes place in one of a large calibre.

In all cases of punctured wounds of small arteries, and particularly when the bleeding has ceased by artificial means, and pressure can be effectively made, and especially against a bone, it should be tried in a graduated manner over the part injured, in the course of the artery above and below the wound, and over the whole limb generally, the motions of which should be effectually prevented, and absolute rest of the whole body enjoined, if the artery is of any importance. This should be continued for two, three, or more weeks, according to the nature of the injury, and for some time after every appearance of recovery has taken place, in order to aid in the consolidation of the parts filling up the opening in the artery.

CASE 1.—A medical student, being desirous of bleeding his friend in the arm, opened the ulnar artery which in this case was very superficial. On discovering the error he had committed, he closed the wound in the skin, and applied a firm compress and bandage, under which it healed, and the edges of the cut artery seemed to be in apposition, as little or no blood had escaped between them. On applying the ear to the part, it sounded like an aneurism, although there was no tumour, the thrilling sound being apparently occasioned by friction against the cut edges of the inside of the artery. This thrilling noise gradually diminished, and was lost as the artery became impervious. The vessel immediately below the wound gradually recovered its pulsation, except at the exact situation of the injury, where none could be distinguished. I have seen the same thing occur in wounds of both the arteries near the wrist, from punctures of a similar size, and I have reason to infer that it has taken place both in the axillary and the femoral arteries.

CASE 2.—The master tailor of the 40th regiment, tempted by the approaching prospect of plunder, was induced, on the night of the assault on Badajos, to give up the shears, and arm himself with the halbert, and was properly rewarded for his temerity

by a wound from a pike in the right arm, from which, he says, he bled like a pig, and became very faint. On his arrival at the spot indicated for surgical assistance he fainted, but this was attributed to the unwarlike propensities of the man, rather than to any sufficient cause. The wound was not more than one-third of an inch long, a little below the edge of the pectoralis major, and immediately over the artery. The arm and hand were numb and cold; the pulse was not distinguishable at the wrist, and it appeared to cease at the place of injury, which was harder and a little more swelled than natural. He said that his pulse had always been felt by the doctors in the usual place. I took him into my house to watch the case, and the wound healed without any trouble, attention being had to keeping the arm warm by covering. On the 1st of May the pulsation of the artery could be felt a little below the wound, and on the 6th it was distinguishable along the lower edge of the biceps. On any exertion he had a good deal of unpleasant numbness in the thumb and forefingers. A small cicatrix formed at the place of the wound, which was otherwise quite natural to the touch. The median nerve may have been injured; that the artery was wounded there can be no doubt, and that it healed without the least assistance from art, although it became impervious at the part injured. This case proves that when a large artery is wounded in man by a sharp cutting instrument, to a certain but moderate extent, the process of cure takes place through inflammation, and by the obliteration of that part of the canal of the vessel. Continental surgeons, and especially the French, have sacrificed whole hecatombs of animals to prove this fact, which had been so many years before recorded in England.

It has not been satisfactorily proved in man that a large artery, such as the femoral, has been opened to the extent of one-third or a fourth of its circumference, and that the wound has healed without the canal becoming impervious. Two such cases are stated to have occurred in the 23rd vol. of the *American Journal of Medical Sciences;* but as the pulsation distinguished in the lower part of the vessel was not perceptible in the first instance, and was only felt after a little time had elapsed, I am disposed to apprehend that dissection would show an obliteration of the canal in each, at the point injured, although it might not be for more than the eighth of an inch in extent. A *small wound* of a large artery may close without obstructing the canal of the vessel, but the part is not so firm or solid as before, and may yield, and give rise to an aneurism, having apparently the characters of a small true, as opposed to the spurious diffused or even circumscribed swelling, which more usually follows a similar accident.

CASE 3.—Colonel F. was wounded by an arrow in the right side of the neck, opposite the bifurcation of the carotid, which caused a considerable loss of blood at the moment. The wound healed, leaving only a mark where the point of the arrow had entered. Some time afterwards he observed a small swelling at the part which, from its pulsation, was declared to be an aneurism. He therefore showed it to Sir A. Cooper, who advised his doing nothing, as it did not increase. Uneasy about it, he asked my opinion at Badajos after the siege. It had not increased, but it caused him some anxiety, and I promised to place a ligature on the common carotid as soon as the campaign was over if it should increase in size. It did not do so, and nothing was done, he being killed in action the year afterwards.

In cases of this kind, and in that of Mr. Chamberlaine's, of Jamaica, in which he tied the axillary artery for an aneurism after a punctured wound to be noticed hereafter, the disease in the vessel seemed to be confined to the part wounded, and to be in reality a true aneurism, from the inner coats not having united firmly, and from the outer coat although united or healed having lost its elasticity, and become dilated—an effect which will, in all probability, follow an injury of an artery, when the obliteration of the canal does not take place. The wound in the artery may communicate with a vein.

CASE 4.—Mr. Keate and Mr. C. Johnson have under their care in St. George's Hospital at present, a young man who received an injury from a knife, on the 28th of October, 1845, as nearly as possible in the inside of the middle of the right thigh, which bled profusely, until he fainted. The wound was then closed, and secured by compress and bandage for between two and three weeks, when on their removal it was found to be healed, but a small pulsating tumour had formed, for which he was sent to the hospital. This was manifestly an aneurism, but from the peculiar thrill it communicated to the touch, and which could be distinguished even above Poupart's ligament in the femoral and iliac veins, it is believed to be a *varicose aneurism*, which is said to be formed when the artery and vein have been both opened, having some cellular membrane as a means of communication between them, and through which the blood is propelled from the artery into the vein. When the blood is propelled directly into the vein so as to enlarge it, the complaint is called an *aneurismal varix*. The man being in bad health all operative methods were considered improper, and under a light but well regulated pressure on the part, the tumour is diminishing in size, is firmer to the touch, the thrill and sound are certainly less marked, and a cure may be effected, although in these cases it rarely occurs without a ligature being placed above and below the opening in the artery.

When an artery in man is cut *transversely*, or to a fourth of its circumference, it forms a circular opening as in animals, and if the artery be large the bleeding usually continues until the person faints, or it is arrested by pressure. The difference between arteries in man and in animals is here strongly exemplified. In dogs the bleeding commonly ceases without any assistance from art, and without the animal being exhausted; in horses and sheep they usually bleed until they die; whilst in man, even with the best aid from compression, hemorrhage will in all probability recur, unless the circulation be altogether stopped. If the external opening only should be closed, a spurious, circumscribed aneurism will be the consequence in so small an artery as the temporal, and I have often been obliged to lay open, and sometimes to apply a ligature above and below a little aneurism of this description. When it has been of a smaller size I have merely divided it transversely, and applied pressure; but there is some danger of the pressure becoming deranged, and of a return of the hemorrhage. In a larger artery the spurious aneurism may or may not be diffused.

When an artery is *completely divided*, it is less likely to continue to bleed than if it had been only wounded, and a variety of opinions have been entertained as to the means employed by nature, as well as by art, for the suppression of the hemorrhage.

In my work on the Diseases and Injuries of Arteries I have quoted the opinions of the most esteemed authorities—on the means employed by nature for the suppression of hemorrhage—from Celsus, Rufus, Galen, and Ætius down to Dr. Jones, the latest and most important of all. The methods they generally adopted appear to me to have been insufficient for and unequal to the object in view. They bled an animal until he died, and then reasoned on the manner or means by which the bleeding was suppressed, when it was in fact arrested by death. It is only when nature has not been interfered with, and the patient has not died from bleeding continued to the last moment, but has on the contrary lived some time after the hemorrhage has ceased, that the processes by which its suppression has been accomplished can be fairly investigated. These processes essentially depend on the size and variations of structure in an artery. They are dissimilar in large and small arteries, and not even quite alike in the upper and lower ends of the same artery—facts which were elicited from observations made on man on the field of battle during the Peninsular war, and consequently not liable to error.

Arteries of moderate dimensions, such as the femoral or axillary, tibial or brachial, and particularly all below these in size, are capable by their own intrinsic powers when completely divided, of arresting the passage of the blood through them without any assistance from art, or from the surrounding parts in which they are situated. This fact overthrows at once the whole theory which relates to the importance of and necessity for the sheath of the vessel, and the offices it performs in suppressing hemorrhage; and in a great measure, to that supposed to be derived from the formation of an external coagulum, the *bouchon* of the French.

CASE 5.—A soldier who had his arm carried away by the bursting of a shell at the siege of Ciudad Rodrigo, was brought to me shortly afterwards. The axillary artery becoming brachial, was torn across, and hung down lower than the other divided parts, pulsating to its very extremity. Pressed and squeezed in every way between my fingers in order to make it bleed, it still resisted every attempt, although apparently by the narrowest possible barrier, which appeared to be at the end of the artery, and formed by its contraction. The orifice of the canal was marked by a small red point, to which a very slight and thin layer of coagulum adhered, the removal of which had no influence on the resistance offered by the very extremity of the artery to the passage of blood through it. In this, and in another instance of a similar nature, I cut off the end of the artery at less than an eighth of an inch from the extremity, when it bled with its usual vigour. In both, the vessel for near that distance was contracted so as to leave little or no canal at its orifice, which in those cases was filled by a coagulum of the size and shape of a very small pin.

CASE 6.—During the battle of Salamanca a soldier was brought to me whose leg had been carried away by a cannon-shot. I found the posterior tibial artery pulsating to its extremity in a similar manner. As he had lost a considerable quantity of blood, and was much discouraged, I did not try to make it bleed, but amputated the leg forthwith, and examined the artery afterwards. I have had many opportunities of seeing the same thing, and therefore assert that it is in the very extremity of the cut artery that the power or means of suppressing hemorrhage resides after the vessel has been divided. In many cases of amputation, in which I wished the patient to lose a certain quantity of blood, I have allowed an artery to bleed until it ceased. The jet in such cases appears to be propelled at first irregularly, or by jerks, the stream then becomes continuous, although acquiring a little impulse from each contraction of the heart. As the orifice contracts, the flow of blood becomes more equal, it is thrown to a less distance, the size of the stream is smaller, and it goes on diminishing until at last the blood only oozes out, and by the time it ceases altogether to be discharged, the extremity of the vessel is covered by a thin layer of coagulum, which is readily removed from it. In many cases in which I have examined the parts after death or after amputation, in consequence of disease below the injury of the artery, this contraction of the vessel was evident, as well as the formation of the very thin layer of external coagulum, extending like a fine red thread into the canal of the artery. The sheath of the artery could, in the cases related, do nothing, because it was carried away—it was not present—neither did the internal coagulum, on which so much stress has been laid, because at this period, strictly speaking, it does not exist.

In small vessels, such as the radial or ulnar arteries, little depends on the diminished power of the circulation; but when the axillary or femoral artery is divided, the shock of the injury and the loss of blood, powerfully contribute in the first instance to the suppression of hemorrhage, by subduing if not momentarily arresting the action of the heart. Having thus established the fact by observation and experiment on man, that arteries in the extremities of the second order in regard to size, will cease to bleed through their own efforts, unaided by the assistance of the surrounding parts, I am far from intending to imply that no assistance is ever given by the surrounding parts when the femoral artery is cut across high up. When an artery of this size is divided in situ, and retraction has taken place, the wound in the limb being small and not direct, the assistance is oftentimes considerable, although it is only auxiliary by retaining the coagulated blood in its place against the ragged orifice of the contracting vessel. If the axillary artery be laid bare previously to an operation for amputation at the shoulder, and the surgeon take it between his finger and thumb, he will find that the slightest possible pressure will be suffi-

cient to stop the current of blood through it. Retaining the same degree of pressure on the vessel, he may cut it across below his finger and thumb, and not one drop of blood will flow. If the artery is fairly divided by the last incision which separates the arm from the body, without any pressure being made upon it, it will propel its blood with a force which is more apparent than real. All that is required to suppress this usually alarming gush of blood, is to place the end of the forefinger directly against the orifice of the artery, and with the least possible degree of pressure consistent with keeping it steadily in one position, the hemorrhage will be suppressed. It is more important to know, that if the orifice of the artery from a natural curve in the vessel, or from other accidental causes, happens at the same time to retract and to turn its open orifice a little to one side, so as to place it in close contact with the side or end of a muscle, the very support of contact will sometimes be sufficiently auxiliary to prevent its bleeding.

In amputation of the hip-joint, the femoral, and profunda arteries are usually divided at, or just below the origin of the latter, and bleed furiously if disregarded; but the slightest compression between the finger and thumb stops both at once. They never have given me the smallest concern in these operations, or others of a similar nature, and I have learned to hold all arteries that can be taken between the finger and thumb in great contempt. It is quite impossible for a man to be a good surgeon—to do his patient justice in great and difficult operations attended by hemorrhage unless he has this feeling—unless his mind is fully satisfied of the truth of these observations. Whilst his attention ought to be directed to other important circumstances, it is perhaps absorbed by the dread of bleeding, by the idle fear that he will not be able to compress the artery and restrain the bleeding from it—that he may have half a dozen vessels bleeding at once—that his patient will die on the table before him. Once fairly in dismay, and the patient is really in danger; but, endowed with that confidence which is only to be acquired through precept supported by experience, he surveys this scene with perfect calmness; taking the great artery between the finger and thumb of one hand, he places the points of all the other fingers of both if necessary, on the next largest vessels; or he presses the flaps or sides of the wound together until his other hand can be set at liberty by an assistant, or in consequence of a ligature having been passed around the principal artery. I admit that this is a scene sufficient to try the presence of mind of any man; but he is not a good surgeon who is not equal to it—who does not delight in the recollection of it when his patient is in safety, and his recovery assured. I have seen many persons die on the table under great operations. I never lost one from hemorrhage, except in one instance in which a tourniquet was applied. It was with no small satisfaction I heard a gentleman some six months ago, publicly state in the board-room of the Westminster Hospital, that the surgeons of another hospital to which he was especially attached, never used a tourniquet in amputation, and declare it to be an indication of their superiority over those who did resort to it for assistance. Joining most cordially in the approbation thus bestowed, I could not but feel gratified in recollecting that I was the first who publicly taught this method of proceeding; and it must be highly satisfactory to those governors who take an interest in the character of the Westminster Hospital to know that it was under their auspices and in their hospital it was first practised in London. It was in consequence of this recommendation that my old friend, Sir Charles Bell, whose loss to science cannot be too much regretted, represented me seated on a pack-saddle on the back of a bourro (*Anglice*, a jack-ass), on the top of the Pyrenees, expatiating on the merits of these barbarous proceedings to the descendants of the Bearnois of Henri Quatre with one hand, and to the children of the lieges of Ferdinand and Isabella with the other.

When the femoral artery is *cut across* in the upper part of the thigh, whether it be done by a cannon shot, a musket ball, or a knife, the patient does not always bleed to death at once, although he frequently dies after a time in consequence of the shock and the loss of blood. He is less likely to die if the artery is divided in the middle or lower half of the thigh, but in both cases it is probable the hemorrhage will cease of itself. If it should recur, it will be more likely to take place from the lower than the upper part of the artery, on account of the different process adapted by nature in these cases—facts, the knowledge of which we also owe to the war in the Peninsula.

Case 7.—At the battle of Toulouse, a large shot struck an officer and two men immediately behind him, and nearly tore off the right thigh of each. The artery was divided about, or less than three inches below Poupart's ligament. I saw him shortly afterwards in consequence of his surgeon saying it was a case for amputation of the hip-joint. The pulse was feeble, the countenance ghastly, bedewed with a cold sweat, and with every indication of approaching dissolution. The house being at an advanced point, and close to one of the French batteries, the fire of round shot and musketry was so severe upon and around it, as to induce me to remain until the battery should be taken by the troops then advancing upon our flank. In order to occupy my time usefully, I returned to the officer, and found he had just expired. Desirous of seeing by what means the hemorrhage had been arrested, I cut down upon the artery, took it carefully out, and found that its divided end was irregularly torn; a slight contraction had taken place just above, but not sufficient to have been of the slightest utility in suppressing the bleeding, which was in fact prevented by an external coagulum which filled up the ragged extremity of the vessel, and which in a few days would have been removed with the purulent discharge. The orifice of the artery, and the surrounding surface for at least an inch in extent would then be covered by a yellowish green-coloured matter, very distinct in appearance from the natural structure, and so strongly marked as to point out the situation of the extremity of the artery.

Case 8.—At Salamanca I had the opportunity of examining the thigh of a French soldier, whose femoral artery had been divided perhaps even higher up by a cannon shot. He lived until the next morning when I saw him, no operation whatever having been attempted, nor a tourniquet applied. He died exhausted, but not from any immediate bleeding, which when once stopped had not returned. The artery was in a similar state to the preceding one, with this slight difference, that the orifice was a little more contracted, the external coagulum filled up the ragged end of the artery, and was slightly compressed within by the contraction which kept it in its place. The rest of the coagulum filled the hollow in the surrounding parts which the retraction of the artery had occasioned. In this case, so unlike those I have hitherto noticed, the first natural cause giving rise to the suppression of the bleeding was the diminution of the power of the heart; the second the formation of a coagulum in the hollow of the sheath left by the retraction of the artery. Contraction had begun, but had done nothing essential.

If a case of this kind should survive, and the hemorrhage should be ultimately restrained by natural causes, I am led to surmise from what I have seen in the artery a little lower down, that the continued contraction which occurs in a circular direction just within the rugged or torn end would gradually lead to the protrusion of the external coagulum, projecting into its canal, like a mamillary process—an operation which would be assisted by the lymph or fibrin poured out from within and around the artery.

In other instances in which I have examined the extremities of such large arteries when divided, the appearances have been more or less of a similar nature; unless where the persons had died immediately, when the torn extremities were found quite open and with little surrounding coagulum.

The processes of nature are different in an artery of a somewhat smaller calibre. When the femoral artery has been fairly divided in the middle or lower part of the thigh, the patient has, in almost all the cases which have come under my observation, either died without assistance, or the hemorrhage has ceased spontaneously. Having been arrested for twelve hours, the efforts of nature are usually sufficient to prevent its return from the upper, although not from the lower end of the vessel; but then it is of venous and not of arterial colour—a fact now acknowledged to be of the greatest importance. The great evil to be dreaded in such cases, is not from hemorrhage from the upper end of the divided artery, but from the lower, and from mortification of the foot, which circumstance I shall notice in its proper place.

The upper end of an artery retracts on being divided, and this retraction is accompanied by a contraction of the cut extremity of the vessel, which assumes the shape of the neck of a French wine-bottle or Florence oil-flask. The contraction is confined in the first instance to its very extremity, so that the barrier opposing the flow of blood is formed by this part alone. The contraction goes on, however, increasing for the space of an inch, which is usually filled up with an internal coagulum, of a round pyramidal shape, adhering firmly to the contracted end of the artery, loose at its apex, and extending frequently as far as the first collateral branch, but rarely under any circumstances beyond two inches; the very orifice of the artery on the outside being in a few days covered by the yellowish green-coloured matter I have already alluded to. Some of these processes are continued even after the external wound has healed; the artery goes on diminishing and contracting as far as it is useless, so that of four or five inches, from one to two may be impervious, the remainder being contracted although still permeable by a probe. An accompanying nerve where there is one would do the reverse, the cut extremity would be enlarged or bulbous, gradually diminishing as it is traced upwards, until it becomes of its proper size.

The processes adopted by nature for closing the end of the lower extremity of an artery of the size of the femoral at the inferior part of the thigh, are different from those employed at the upper or opposite extremity. The retraction or contraction of the lower end of a divided artery is neither so perfect nor so permanent as at its upper end, and the small internal coagulum is in many instances altogether wanting or very defective in its formation. The closure of the lower orifice being less perfectly accomplished than the upper, it is the most likely to suffer from secondary hemorrhage, which may be distinguished from that from the upper end of the artery at an early period after the accident, by the venous colour of the blood, and from its flowing or welling out in a continuous stream, as water rises from a spring, and not with an arterial impulse.

The retracting and contracting powers in the lower end of a divided artery are, nevertheless, considerable, and are sufficient in some cases to nearly close the lower end of the femoral artery when divided by amputation above the knee. When the femoral artery is cut across, the lower portion of the vessel is emptied by its last efforts, combined with the action of the capillaries. When the collateral circulation is powerful, blood soon regurgitates into the artery, but the force of the regurgitation can be in no proportion to that of the propulsion at the other or upper divided end of the vessel, which will generally be able to resist this impulse; whilst the lower one oftens opens and bleeds after the lapse of a few days. In all the cases I have had an opportunity of examining, in which hemorrhage had taken place from the lower end of the artery, the following appearances were observable after the lapse of a few days:—

The same kind of yellowish-green matter marks and conceals the situation of the lower extremity of the artery as it does the upper. It is however thinner where it immediately covers the end of the artery, which in none of these cases is contracted in the conical manner described as taking place in the upper extremity. On the introduction of a probe with the greatest gentleness into the artery from below, it usually makes its appearance at a point on the yellow space, raising a thin portion as it protrudes. On laying open the artery, the orifice would seem to have been once closed by this layer of fibrin, but with a less degree of contraction than the upper end of the same artery; the layer still however forming an obstacle sufficient to cover and close three-fourths of the orifice, the blood having flowed through the remaining fourth, which had probably given way by accident. The following

case is illustrative of the several points alluded to.

Case 9.—Serjeant William Lillie, of the 62nd regiment, aged thirty-two, was wounded in the right thigh, on the 10th of April, at the battle of Toulouse, by a musket-ball, which passed through, in an oblique direction downwards and inwards, close to the bone, describing a track of seven inches. The ball was extracted behind on the field. He said he had bled a good deal on the receipt of the injury, which he had stopped by binding his sash around the limb. The discharge from the wound was considerable; it appeared, however, to be going on well until the 20th of the month, when, on making a sudden turn in bed, dark coloured blood flowed from both orifices of the wound in considerable quantity. I had given an order as chief of the medical staff in Toulouse, that no operation should be performed on a wounded artery without a report being sent to me, and an hour at least granted for a reply, unless the case were of too urgent a nature to admit of it. It appeared to be so in this instance, and before I arrived Mr. Dease had performed the operation for aneurism at the lower part of the upper third of the thigh. I could only express my regret that it had been done, and point out the probability of the recurrence of the hemorrhage from the lower end of the artery, which took place on the 7th of May, when the limb was amputated, and the man died. On examination the artery was found to have been divided exactly where it passes between the tendinous expansion of the triceps and the bone. The upper portion of the artery thus cut across was closed. A probe introduced into it from above would not come out at the face of the wound, although the impulse given to this part on moving it was observable in the middle of a large yellowish-green spot, which I had previously declared to be the situation of the extremity of the artery, which had contracted behind this, in the shape of a claret-bottle for about an inch, having within it a small coagulum. The lower end of the artery from which the hemorrhage had taken place was marked by a spot of a similar character; but on passing a probe upwards from the popliteal space, it came out at a very small hole in the extremity of the artery, in the centre of the yellow spot, the canal of the artery not being contracted and diminished, but only apparently closed by a layer of the yellowish-green matter laid over it, and adhering to its circumference.

Case 10.—A soldier of the German heavy cavalry was wounded nearly in a similar manner at the battle of Salamanca, and died in the night, some days after the injury, from inattention. The appearances were nearly the same, and I have had so many opportunities of verifying these points, that I do not hesitate in considering the following as three important facts, first demonstrated and proved during the war in Portugal, Spain, and France, and that nothing has since occurred to impeach their accuracy.

1. That an artery as large as the femoral is capable, when divided, of taking on certain processes, which will cause a suppression of hemorrhage from its upper end, and which suppression is usually permanent.

2. That the bleeding from the lower end of the same vessel is less certainly and less permanently restrained, and not by exactly similar processes; the blood issuing from the lower end of the femoral artery being for the first few days of a venous colour. It is less so from the axillary artery, in consequence of the collateral circulation in the upper being more free than in the lower extremity, and the change of colour is sometimes not perceptible in the smaller arteries of the forearm, although it is generally so in those of the leg.

3. That this bleeding from the lower end of the vessel, which is more or less of a venous colour, and issues in a continuous stream, may be restrained by compression properly made on, and in the course of the lower part of the wounded artery; but that in no instance should recourse be had to a ligature on a distant part of the artery above the seat of injury, until every other possible effort to arrest the hemorrhage has failed.

Apothecaries' Hall.—Professor Brande will commence his Course of Lectures on Friday, May 1.

A Course of Lectures on Hernia,

By JOHN FLINT SOUTH, Esq.,

Surgeon to St. Thomas' Hospital, and Professor of Surgery to the Royal College of Surgeons.

(Delivered in the Theatre of the College, and revised by the Professor for the Medical Times.)

Lecture II.

General observations on irreducible or incarcerated ruptures:—Symptoms; Causes of incarceration; Most common forms in which incarcerated hernia occurs:—Treatment of incarcerated hernia; Suspension; Pott's observations; Liability of incarcerated hernia to become strangulated; Pott's observations:—Is it possible to do anything for the return of incarcerated hernia? Cloquet's opinion; Views of Hildanus, Le Dran, Pott, Hey of Leeds, and Arnaud; Remarks of Petit and Schmucker; Review of opinions by Professor South.

General observations on strangulated ruptures:—Definition; Symptoms; Cause of the vomiting; Flatulence; Tightness in the midriff; Dragging at the pit of the stomach; Tenderness of the abdomen; Tympanitis; Wiry pulse; Peritonitis; Hiccough; Sunken Countenance; Swelling soft and doughy; Death.

General Observations on Irreducible or Incarcerated Ruptures.

Symptoms.—A swelling capable of increasing size or dilatation by the mere effort of coughing, sneezing, or any more violent exertion, is equally a sign of incarcerated, as it is of reducible rupture, but the distinction between them is that the latter returns, or can be returned into the belly, whilst the former remains permanently in the rupture-sac, and neither returns nor will be returned into the belly. It may be, indeed, that more bowel is in the sac at one time than at another, owing to some accidental cause, and consequently that this moves in and out of the sac; but a certain portion never leaves it, yet, although thus retained, it does not ordinarily interfere with the functions of the alimentary canal, and therefore produces no more constitutional disturbance than if it were reducible.

A rupture may become irreducible or incarcerated, when of long standing and great size, from the circumstance of the cavity of the belly being too small to receive it. The person not having worn a truss, or one which was insufficient for the purpose, the pressure of the abdominal muscles, under common exertion, upon the bowels, gradually forces more and more of them into the rupture-sac, which, having no muscular covering of sufficient strength to oppose their admission, and in most instances no muscular covering at all, yields, and increases in size in corresponding proportion to the escaping bowel, which, finding itself freed from any pressure of consequence, soon accommodates itself to its new situation; whilst the cavity of the belly not merely is diminished by the contraction of the muscles, which becomes permanent upon the lessening quantity of the still naturally remaining bowels, but also by a continual departure of more and more of the peritoneal lining of the muscular cavity of the belly, through the opening of the rupture, for the enlargement of its sac. Hence, in large ruptures, which are perfectly unattached to their sac, it is impossible to return them, because the abdominal peritoneal cavity is not sufficiently capacious to receive them; consequently they must be included among incarcerated ruptures. A rupture may become irreducible or incarcerated by fibrinous bands stretching from one part to another of the interior of the sac, and so entangling without constringing it, that it cannot return into the belly. Or, gut may in like manner be entangled in omentum, which has descended with it, either in a coil which has accidentally got round it, or by bursting through the protruded omentum. Or the rupture sac itself may burst, and the bowel escaping through it may be then confined and unable to return. But the most common cause of incarceration is adhesion between the rupture-sac itself and the peritoneal covering of the protruded bowel, which usually results from the pressure made on them by an ill-fitting truss, and irritates sufficiently to excite a slow inflammation, by which the bowel and sac are united more or less completely. These adhesions vary in length according to the time they have existed, the peristaltic movements of the bowel constantly pulling on and tending to lengthen them.

Another cause of incarceration is to be found in the growth of the protruded part after it has established itself in the sac. This especially applies to the omentum, which, from the comparative bulk of the part in the sac, with that at the mouth of the sac, cannot be explained any other way.

Umbilical is the most common of irreducible or incarcerated ruptures, in consequence of its more frequent original existence; and next to it femoral rupture in women, as they too frequently, from mistaken ideas of modesty, conceal their disorder, and, employing no remedy, allow the protruded bowel to remain constantly down, under which circumstances adhesions of omentum frequently occur.

Treatment.—In the majority of cases, the only treatment employed is the support of the rupture, and the prevention, as far as possible, of its increase, both which objects are at once effected by a suspensory bandage which should lace so as to fit well, and produce equal pressure, or by a truss having a cup, in place of a pad, corresponding in size to the swelling, according to the part at which the rupture is situated.

Pott, in speaking of the large collections of fluid frequently noticed in old omental ruptures which have been only suspended by a bag truss, says, "the fluid is seldom so much in quantity as to occasion any particular attention to it; but, on the other hand, it sometimes is so much in quantity as to become an additional disease to the original one. He had, therefore, more than once been obliged to let it out, in order to remove the inconvenience arising from its weight, and the distension of the scrotum, which he had also seen become gangrenous by the neglect of this operation." Such occurrences, I apprehend, are very rare, and unless gangrene existed, I should not be disposed even on Pott's high authority to open the sac and draw off the water, for fear of the inflammation which might attack the sac, spreading to the general peritoneal cavity. Although an incarcerated rupture does not usually produce any constitutional disturbance, yet must it be always considered as predisposing to strangulation, and, therefore, is of more consequence than one which is reducible. Upon this point I cannot do better than quote Pott's observations. "It is fit" says he, "that mankind should be apprised, that the quiet, inoffensive state of this kind of hernia is by no means to be depended upon; many things may happen to it, by which it may be so altered as to become hazardous, and even fatal. An inflammation of that part of the gut which is down, any obstruction to the passage of the aliment or fæces through it, or a stricture made by the abdominal tendon, either on what has been long down, or on a new portion which may at any time be added to it, is always capable of so altering the state of the case as to put the life of the patient in danger. Indeed, the hazard arising from a stricture made on a piece of intestine contained in the sac of an old irreducible hernia, is in one respect greater than that attending one that has been found at times reducible; since, from the nature of the case, it will hardly admit of any attempt towards relief but the operation, and that in these circumstances must necessarily be accompanied with additional difficulty."

The possibility of the occurrence of such serious conditions in cases of irreducible incarcerated rupture renders it a very natural question, whether it be advisable to do any thing for their return. If the bowel be either entangled by bands or the gut by the accompanying omentum, or if the bowel have contracted adhesions to the sac, no treatment will be serviceable; nor do I believe, as Cloquet affirms, that there may be a spontaneous cure by the retraction of the peritoneal sac into the belly, which, if the rupture be of large size and long standing seems to me utterly impossible. But when the bulk of the swelling is omental, treatment which is more specially directed to the diminution of its size may occasionally be successful. Pott quotes from Hildanus the case of a man who was radically cured by six months' confinement to bed, in the case of a rupture of twenty years' date. And Le Dran says, "I have seen the late M. Arnaud reduce several

of these herniæ of long standing, and keep them so; and I have known the patients live many years afterwards in good health, and free from those accidents that might have been apprehended. The reason of this success was that the precautions he took to facilitate the reduction conduced also to the preservation of them from those accidents that might have happened after the reduction was made. These precautions consist in confining the patient for a fortnight or three weeks to his bed, during which time he is to live entirely on soup and broths, and even of those in such quantity only as to prevent inanition. It would be proper, likewise, he should be blooded three or four times, according to the ulness of his constitution, and have his body kept open with gentle purgatives. By these means his strength being diminished, the parts become more pliable, and the whole body being emaciated, the size of the mesentery and epiploon is likewise lessened, whose bulk was the principal obstacle to the reduction. It is then more easy to replace the parts in their natural situation, which being once done, there is no great difficulty in keeping them there." The latter part of Le Dran's proceeding is, to use a common observation, much more easily said than done, as the mouth of the sac still remaining little, if at all, diminished, and the part in which it is, being very lax from the general emaciation. But little effort will be needed to reproduce the rupture. "This method," says Pott, "has now and then succeeded, and in some cases is worth the trying, but previous to the attempt, there should be one circumstance which makes success probable, and there should also be good reason to believe that the habit and age of the patient will bear the necessary confinement and evacuation; otherwise, though he should get rid of his rupture, he may be much worsted by the experiment. If such attempts succeed," he observes, "a truss should be immediately put on, and worn constantly without remission; for in these people the largeness of the abdominal aperture, the thickness of the hernial sac, and the relaxation of the mesentery, make a new descent always to be apprehended and guarded against." Hey, of Leeds, followed Arnaud's practice, and has mentioned several successful cases in his Practical Observations on Surgery.

But if the return of a rupture, incarcerated by its size, can be thus effected, yet it appears to be questionable whether it be prudent to replace a large rupture, though it may be returned without much difficulty. Petit justly observes, "it is always dangerous to return into the belly a large quantity of parts which have been long in a rupture, whilst the belly, as it may be said, has accustomed itself not to contain them; so that, when returned to their original place, they are, as it were, foreign to it. And this is not the least, I have seen a person die after the reduction of a large rupture by the taxis alone; he had inflammation of the whole belly, and many intestines were gangrenous; after the reduction he had symptoms of strangulation, although no strangulation existed." "In another patient, who had an omental rupture of considerable size, it was reduced without much effort, I might even say with readiness, although for six weeks it had not returned. The patient could not bear the bandage applied, but pulled it off immediately as nausea, and afterwards vomiting, ensued. He complained of dull pain over the whole belly, accompanied with so great degree of oppression, that, not doubting these were caused by the reduction of the parts, attempts were made to reprotrude them, but in vain; neither the vomiting nor supervening convulsions could force them out. At last inflammation of the whole belly, fever, and pain, became so severe that he died after forty-eight hours of suffering. On opening the body, we found all the parts of the belly inflamed and almost gangrenous, the portion of omentum which formed the swelling, like a pad resting on the edge of the sac, the aperture of which was closed by peritoneal inflammation." That the reduction of the rupture was, in these cases, the cause of death, and that in neither instance was it accidental, is proved by Schmucker's observation of a man of two-and-thirty years old, who from youth had an inguinal rupture, but which, having been neglected, had become of immense size, the abdominal ring very large, and the abdominal muscles exceedingly contracted. After purging and low diet, on the afternoon of the tenth day, he reduced the rupture with much trouble, because the abdominal muscles would not yield, and applied a good truss; he was directed to take cream of tartar, and have the belly rubbed with oil, and keep in bed. I had not yet left him, when he cried out that he could not long bear it, as it was as painful as if the belly would burst. I encouraged him with the hope that it would soon be otherwise, but, on the following morning, he assured me he had suffered such pain during the night that he would have the bandage removed. The oppression, however, increased, so that he almost fainted, and could scarcely breathe. I ordered an analeptic potion, drew up his knees, and raised his head and chest so as somewhat to diminish the tension of the belly; this was continued, but in the evening I found him almost at the last gasp. The pulse was small and scarcely to be felt, the face covered with cold sweat, and the patient and his friends earnestly begging me to remove the truss; I at last consented, as I saw that, under present circumstances, it was impossible he could bear it any longer, that his friends would remove it, perhaps with carelessness, and that then the intestines might protrude violently and cause mischief. I therefore loosened the bandage, put my left hand between the part and the rupture, and allowed it gradually to descend; scarcely had a bit of it escaped, when the patient again breathed, and after a quarter of an hour the rupture was as large as ever, and the patient again brisk and well."

The recital of these interesting cases proves the danger of returning large old ruptures into the belly, which is unfit to receive them, as well from its insufficient capacity as from the resistance which its muscular walls offer, and shows that the best treatment is simply to support and prevent the enlargement, as far as possible, of the rupture, by a well-fitting suspensory bandage. The starving and recumbent system will, indeed, in time permit the return of the rupture, if it be principally omentum, and in persons who have only to live a life of ease and quietude. But if intestinal, and in labouring persons, who must again be exposed to exertions such as have originally caused the rupture, it seems to me little likely to be of permanent benefit, as the mouth of the sac will not contract so as to prevent the escape of the bowels, and, by time and laborious exertion, it will probably again resume its former size.

General Observations on Strangulated Ruptures.

A strangulated rupture differs from an irreducible or a reducible rupture in not being returnable like the latter; and although unreturnable, like the former, yet differing from it as it interferes with and suspends the functions of the bowels, and presents a train of symptoms which especially distinguish its condition.

Symptoms.—The symptoms of a strangulated rupture are a hard unyielding swelling on the belly or its immediate neighbourhood, and more or less inelastic, according to its actual distension, whether the swelling be small or large. It is usually accompanied with costiveness and vomiting; sometimes both equally severe, at other times one more violent and obstinate than the other. The costiveness depends on the intestinal passage being obstructed, so that the contents of the bowels, having reached the strangulated part, can pass no farther. But if the intestine below the strangulation be loaded with fæces previously to the occurrence of strangulation, it may and frequently is capable of emptying itself, and therefore not unfrequently, for a time, motions are passed, although the communication between the lower and upper part of the alimentary canal be entirely cut off. The vomiting depends on two circumstances. The less important one, though it may be exceedingly distressing, is when a portion of omentum has passed into the rupture-sac, and its return being either partially or completely prevented, it is stretched like a cord between the rupture-sac and the stomach, which cord being swayed about by the movement of the intestines, is continually pulling upon and irritating the stomach, so as to excite it to reject its contents. That such is one of the causes of vomiting, is proved by the case related by Pott, in which, in a person who laboured under omental rupture, and found it difficult to keep it up with the best truss he could have, it occasionally slipped down behind, and "when this happened, it gave him such immediate and acute pain at his stomach, and made him so intolerably sick, that he was obliged immediately to throw himself on his back, and procure the return of the piece of omentum." So well marked a case as this does not, it is true, very often occur, but it nevertheless clearly shows that the pulling of the stomach by the omentum in the sac is one of the causes of vomiting in strangulation. This state of things may exist without any obstruction of the intestinal canal, although, however, it may happen that omentum which has passed into a rupture-sac, may so confine an intestine even within the cavity of the belly, as entirely to cut off the lower from the upper part of the alimentary tube. The more common cause of vomiting under strangulation is the actual closing of the intestinal passage by the mouth of the sac, into which the rupture has been thrust, or by some band in the interior of the sac passing across it, or by entanglement in omentum, which has also found its way into the sac. In either of these cases the result is the same, as if a cord were tied tightly around the intestine so as to close its tube. The contents of the stomach and upper part of the alimentary canal are for a time carried along by the peristaltic movement, till they reach the seat of obstruction, but being unable to proceed further, the peristaltic action is reversed, and the intestinal contents are carried back and poured into the stomach. It would seem that this inverted action is speedily propagated from the strangulated part to the stomach; for first there is simple vomiting of the contents of the stomach, afterwards bile is thrown up, and this is followed by ejectment of what is called feculent matter, though that it is really such I much doubt, as in by far the greater number of cases, the small and not the large intestines are those which are strangulated, and fæces are not formed till the contents of the alimentary canal have reached the latter, and received the secretion of the so-called appendix cæci. The simply offensive smell, and the yellowish or greenish, more commonly the latter, coloured matter which is thrown up, is not necessarily, nor is it usually fæces, but merely chyme, with the addition of the biliary secretion and the emptying of the gall bladder, which is specially excited to pour out its contents, as it were, to induce more active efforts in the intestine to perform its ordinary function, which, it being unable to do in consequence of the strangulation, the additional quantity of bile only still further promotes by its irritating properties the disturbance already set up.

In proportion as the stomach is irritated by the vomiting, its functions are also disordered, and hence flatulence is produced, and the patient belches up almost continually large quantities of air. To the distension of the stomach with air, may probably be attributed the sensation of tightness at the midriff, often, though not always, present during strangulation, and which is not unfrequently felt in vomiting under ordinary circumstances. The dragging generally felt at the pit of the stomach during strangulation may either depend directly on the pulling of the omentum, which is one of the causes, as I have mentioned, of vomiting, or upon the pulling of the mesentery when the intestine is strangulated.

The continuance of the vomiting, frequently increased by the patient taking fluid to quench his thirst, or by the too frequent practice of giving purgative medicine to excite the intestines to a duty which they are mechanically incapable of performing, soon breaks down the strength and spirits; the countenance becomes distressed and haggard, and the pulse quick, small, and feeble — all which symptoms are to be attributed to the state of depression from the sickness, either squeamishness or actual vomiting, rather than to any other cause. As the case proceeds there is soreness of the belly, at first probably arising from the violent and repeated action of the muscles in vomiting; but subsequently this is converted into tenderness on pressure, and even pain more or less severe and constant, without pressure, but increased by it; the belly also becomes tense and not unfrequently tympanitic, and the pulse hard and thready, like a wire beneath the finger—symptoms indicating the

presence of inflammation of the peritoneum, which, originating at the seat of strangulation, spreads more or less quickly over the whole cavity of the belly and its contents. Hiccough is not unfrequently present; this has been often mentioned as a symptom of mortification of the rupture; but I have so frequently seen it come on very early after strangulation, and without any mortification, that I think it can scarcely be so considered with justice. After a period of less or greater duration, according to the severity of the strangulation, the patient becomes easy, and the vomiting sometimes, but not always, ceases, and it might incautiously be presumed that this is a favourable change, but it is the very contrary, and affords strong presumption that mortification has ensued, and the case is fast hastening to a close.

The patient's condition is still more alarming if the countenance be sunken and pallid, the face and limbs bedewed with clammy sweat, and the pulse become feeble, smaller, and slowly imperceptible; and if, in addition to this, the swelling, previously hard and unyielding, become soft, doughy, and crackling, and sometimes even subsides, then there is little doubt that the protruded bowel has mortified, and that it has even given way, and emptied its contents into the sac, and perhaps into the belly also. Death soon follows.

GREAT MEETING
OF THE
NATIONAL ASSOCIATION OF GENERAL PRACTITIONERS
IN
MEDICINE, SURGERY, AND MIDWIFERY
AT THE
HANOVER SQUARE ROOMS, HANOVER SQUARE, APRIL 17, 1846.

An exceedingly large and influential meeting of the members of this Association was held on Friday evening last at the Hanover Square Rooms, in pursuance to advertisement, to receive a Report from the Committee, and to consider the propriety of forming a National Institute of Medicine, Surgery and Midwifery. The meeting was very numerously attended, there being at one time about 700 gentlemen present. Among these were Messrs. Pennington, Squibb, Fuller, Bowling, Bonney, Streeter, Bedingfield, Sparkes, Randall, Wooldridge (Southampton), Webster, Baker, Lavies, Merriman, Davis (Hampstead), Hardwick, Craddock, Eyles, Tegart, Bird, Dodd, Vickers, Ancell, Clifton, Stocker, Dale, Hammerton, Headland, Maclure, Martin (Reigate), Semple, Smith, Webster, Wheeler, Cooke, Daniell (Newport-Pagnell), and Miles Beale.

It was moved, seconded, and carried unanimously, that R. R. Pennington, Esq., take the chair.

The chair having been taken, it was announced by the secretary that a very large number of letters had been received from various parts of the country, expressive of the confidence of the members in the proceedings of the committee, and that the following provincial members of the committee, honorary secretaries, and members of the Association, in some instances representing large sections of the Association, had signified their intention of being present at the meeting:—Thomas Haffenden, Hanwell; — Tyson, Newmarket; R. J. Peck, Newmarket, honorary secretary; J. C. Hall, East Retford; Richard Caton, Bradford, Yorkshire; J. H. Norton, Shirley, near Southampton; J. B. Easton, Stebbing, Essex; William Hore, Shore- [illegible] ford; James Cr[illegible]me, Homerton; D. Hock, Mill-Hill, Hendon; R. G. Broxholm, Sunbury; W. Richardson, Highgate; H. Dixon, Cricklade; E. George, Sandgate; J. R. Monday, Ulverston; T. Tomkin, Witham; W. F. Haines, Pinner, near Watford; E. S. Shearman, Rotherham; W. Chaldecott, Dorking; J. Howell, Wandsworth; D. Morris, Colchester; Henry Storer, Bath; H. Wooldridge, Southampton (representing the Southampton branch); G. Rogerson, Liverpool (representing one hundred members of the Association in Liverpool); J. C. Burrows, Brighton; C. Shillito, Brighton.

The President then read the following address:—

Gentlemen,—In again occupying this chair, which I do with heartfelt satisfaction, I feel called on to make a few remarks as to the past and present state of the profession.

Since 1815, now more than thirty years ago, I have continually felt the most lively interest in the welfare of the general practitioners; that interest still continues, and the strongest proof I can give you of the strength of this feeling is that, at this advanced period of my life, I come forward to assist their cause.*

At the time of passing the Apothecaries Act, I hailed it with pleasure as being the first step to enable the general practitioners to assume a decided station of respectability; this has been still unattended with that progressive advancement which so important and useful a body of men deserved.

It is only within the last year that a prospect appeared to open of placing them still higher in the scale of rank their increased attainments, the improved curriculum of education adopted so successfully by the Apothecaries' Society, worthily entitled them to. I allude to the hopes held out by the Secretary of State for the Home Department for granting a charter of incorporation; with the failure of the negociations for that desirable end I conclude you are all familiar.

The able report which you will hear read this evening will inform you of the probable cause of the failure of those negociations, and you will also hear in detail a proposal for the adoption of a line of active conduct which in my judgment cannot fail of being attended with the most marked success in obtaining for the general practitioner that satisfaction which hitherto he has never approached; to that report I call your undivided and earnest attention, fully assured that the lucid explanation contained therein will clear the mist from the minds of all who entertain doubts as to the ultimate success of our great undertaking. (Applause.)

I feel I should be wanting in justice to the Association did I fail to express my sentiments of high appreciation of the conduct of the committee, sub-committee, and honorary secretaries (applause); the unvarying unanimity which has prevailed throughout the entire discussion of so large a body of members, speaks in the highest manner of the character of the gentlemen composing these bodies, and augurs favourably of the intelligence of our class of the profession, and of the result, if, as I confidently anticipate, we shall have the management of our own body. I think it will not admit of contradiction that in no society of men where the interests have been so important had ever more decided feelings of unanimity been shown, more gentlemanly forbearance against unjust aspersions (hear, hear), or more unvarying and steady perseverance in the onward and fruitful path which, up to this time, they have trodden.

After paying my tribute to your committee and sub-committee, I cannot fail to offer the same to your honorary secretaries, Messrs. Bird and Ancell. (Great applause.) I should be wanting in every principle of justice, did I not, in the most unqualified manner, express my feeling of grateful admiration for their untiring and incessant attention to the interests of your Association (applause); the part these gentlemen have taken in the deputation with Sir James Graham merits your highest consideration, and no eulogium of mine can be sufficient to convey the opinion I entertain of these disinterested and valuable services. (Great cheering.)

The undeviating steadiness which all concerned in conducting the affairs of this Association have displayed, is deserving of the highest praise.

In conclusion, I feel proud to affirm my conviction that the same amount of integrity and uprightness which has, up to this time, kept the Association together will continue, and ultimately obtain for its members that honourable distinction to which they are so justly entitled. (Applause). Every influence I, as your president, can exert, shall be employed for the furtherance of the great object; all that is in my power shall be done to assist in carrying out your views; my greatest pleasure will arrive when I am enabled to congratulate this Association on the complete fruition of its hopes. (Great applause, continued for several minutes.)

The Report of the Committee was then read by Messrs. Bird and Ancell, the honorary secretaries.

REPORT.

The committee of the National Association have called the members together, in the first place, for the purpose of making a report of their proceedings; secondly, to direct the attention of the members to some of the more important considerations connected with the present state of the medical question; and, thirdly, to bring under the consideration of the meeting the result of their experience and deliberations as to the future course which the general practitioners of this country are called upon to pursue.

The proceedings of the committee up to the 4th day of March have been printed in the "Transactions" of the Association, and it will be unnecessary to occupy the valuable time of the meeting to any great extent with a recapitulation of their contents. It has at all times been a source of gratification to the committee that the "Transactions" have been generally approved of by the members of the Association, and that they have always appeared to fulfil the special purposes for which from time to time they have been issued, and it gives the committee the greatest pleasure to state that, so far as they can judge from their correspondence and communications with their professional brethren, the last number, which records the more recent proceedings of the committee in their negociations with the government, and expresses unequivocally the sentiments of the committee upon the result of those negociations, has been received by the members at large with equal, if not greater, satisfaction than any previous number.

At the last special meeting of the Association, held on the 6th of May, 1845, the committee reported that they had succeeded in convincing the government of this country that the late attempt at legislation to which the Right Honourable the Secretary of State for the Home Department had become a party, was inimical to the interests of the general practitioners. A principal feature of the contemplated legislation was to create, under the title of "Licentiates in Medicine and Surgery," a distinct and inferior grade of practitioners, whose education was to be placed under the control of the Colleges of Physicians and Surgeons, and who were to be deprived of all hope of, or pretension to, any corporate privileges whatever; with which inferior grade of practitioners the great body of the existing class of general practitioners was to be identified. Subsequently to the representations now referred to by the committee, of which a full report has been furnished to the Association, Sir James Graham admitted the importance of the general practitioners as a class, and the necessity on public grounds of sustaining their character and qualifications; he accordingly called for parties possessed of full power to treat with him on their part, with the view of repairing the error at first fallen into, of promoting the respectability by upholding the qualifications of the great body of the profession, and for the purpose of arranging the necessary preliminaries for the grant of a charter to incorporate the general practitioners in a new institution of a collegiate character, and thereby to provide for this large proportion of the whole profession the rights and privileges which they so justly claim.

The individuals appointed to treat with the Right Honourable Baronet were, R. R. Pennington, Esq., James Bird, Esq., and Henry Ancell,

---

* In proof of his readiness and anxious desire to support and further the cause of the Association, not only by his attendance at the meetings, and his personal service, Mr. Pennington has recently presented a second donation of *one hundred pounds* to its funds.

Esq., on the part of the National Association; and John Bacot, Esq., and John Ridout, Esq., on the part of the Society of Apothecaries; these gentlemen were invested as a joint deputation, with full authority on behalf of the National Association of General Practitioners, to accept or reject such a charter of incorporation as the Crown might be advised to grant, and on behalf of the Society of Apothecaries to relinquish their present privileges as soon as the terms of the proposed charter should be adjusted to the satisfaction of the deputation. Sir James Graham was fully satisfied as to the plenary powers vested in this joint deputation, and treated with it accordingly; the deputation have furnished the Association with three reports on the subject of the negociations subsequently entered into; and these reports have been printed in the "Transactions" of the Association, bearing date May the 17th, 1845, August the 14th, 1845, and March the 4th, 1846; the committee accordingly presume that the members of the Association are fully acquainted with the character, progress, and termination of the negociations with the government. The powers vested by the National Association in the gentlemen who represented it in that deputation are now resigned, and the committee publicly reiterate their entire satisfaction at the manner in which the deputation has sustained the interests and honour of the general practitioners of this country, and their cordial thanks for the exertions they have made to carry out the objects of the Association. (Great applause.)

The members are aware that in these negociations the educational question constituted the real difficulty. Before closing their labours, the joint deputation published the three reports above referred to, in a separate pamphlet, with a preface on that part of the subject, and the committee most cordially concur in the sentiments there set forth, and feel thoroughly convinced that they will meet with the approbation of this meeting, and that they are calculated to impress all parties with the magnitude and importance of the question at issue.

The deputation state:—"The Minister has satisfied himself that it is of the highest moment that the medical attendant of at least nine-tenths of the population should be so educated as to render him competent to the discharge of the duties which the public require at his hands; and that the public have a deep interest in upholding the professional and social status, and elevating the moral and intellectual qualifications of men who are entrusted with the health and lives of thousands of their fellow creatures.

"The deputation have endeavoured to convince the Secretary of State, that it would be unsafe to entrust the education of this body of men either to those who deny, or to to those who tardily and unwillingly admit, that the general practitioner should be educated for all the emergencies of his profession. (Hear, hear, and applause.) It has been asserted that a great mistake was made by the legislature in 1815, in confiding the medical education of the general practitioner to examiners of his own grade; that the education of the class which it was the object of the statute to regulate, has been unduly elevated; and that a wider range of practice has been assumed by that class than the legislature had contemplated, or would have been prepared to sanction. It has been the duty of the deputation to satisfy the minister, that if an error *was* committed by the legislature in 1815, it was an error which it is too late to repair now; that if the effect of that error has been to educate the class more highly than is thought expedient by those who were originally invited to take upon *themselves* the duty of superintending its education, but declined to do so, it is too late for the legislature to retrace its steps; that one of the first effects of improved education on an individual is a desire to see that education extended to others (hear, hear); and that experience has shown that, in the case of the general practitioner, what is true as applied to an individual is no less true as applied to a class; that under such circumstances the only course open to the legislature is the onward course, and that to abandon the exclusive control of the education of the great majority of the medical practitioners of this country to those who, if not actually opponents of the principle of an improved and improving standard of qualification for the general practitioner, have been slow and unwilling converts to it, would be to check the extension of medical science, and to inflict a most serious injury on the great mass of the people." (Great applause.)

"The deputation have taken their stand upon these principles, and they remind the general practitioners that the proposal to entrust them with the education of their own class is an unwelcome proposal in more influential quarters than one. The claim, however, of the general practitioners to a real influence and control over the education and examination of the future members of their own class, when dispassionately considered, tends so obviously to the public good, and the grounds upon which that claim rests are so incontrovertible, that whenever the opportunity arrives (as arrive it must) for a full and fair discussion of the subject by the legislature, there need be little apprehension for the result."

The objects of the National Association have manifestly been twofold, to prevent bad legislation, and to assist in obtaining such legislative changes as are calculated to advance the interests of the public, by promoting those of the large class of medical and surgical practitioners of which the Association is composed. In so far as the Medical Bill first introduced into the House of Commons by the Secretary of State, at the instigation and with the advice and consent of certain colleges is concerned, which Bill, the committee repeat, they sincerely believe was most inimical to the interests of medical science and of the medical profession (hear, hear) in this country, the Association has been completely successful in preventing a defective legislative measure. As respects the second part of their duties, that of obtaining such a settlement of the medical question as would prove satisfactory to the general practitioners, the committee regret that up to the present time their exertions have not been attended with success.

Without entering into details, it will thus be obvious to the members of the National Association, that the profession is in the same position as it was previous to the government undertaking to legislate for it; with, however, one most important exception. By the new charter granted to the College of Surgeons in the year 1843, a deep and immeasurable injustice has been inflicted upon a vast majority of the members of that college (immense applause); the members of the College of Surgeons constituting the largest and most respectable portion of the general practitioners of this country, and of the National Association.

With respect to this new charter and the College of Surgeons, the committee entreat most earnestly that the members will bear in mind how the matter stands. This charter was obtained by the College of Surgeons for the purpose of conforming to the Bill for regulating the Practice of Medicine and Surgery, subsequently introduced into the House of Commons by the Secretary of State for the Home Department; which Bill, as before stated, was effectually opposed by the general practitioners, because with other objectionable matter, and coupled with the charter, it contemplated the institution of an inferior grade of medical practitioners, under the title of "Licentiates in Medicine and Surgery." It has been made plain enough that these practitioners were to be educated for the ordinary exigencies of medical and surgical ministrations, but for these only (hisses, and cries of "Shame, shame"); and, moreover, that the existing class of general practitioners was to be brought down in the eyes of the profession and of the public to the level of these licentiates. Here was a deliberate scheme to lower the standard of education and qualification, and to diminish the respectability of the great body of the profession in this country; and, as respects the practice of surgery in particular, the council of the College have gone so far as to state, not only that they were a party to the intended scheme of licensing persons to practise surgery who would not in fact be fully *competent* as surgeons, but that thousands of the individuals certified by them of late years, as being competent to practise surgery, are fit only to fulfil the ordinary exigencies of surgical art. (Hisses.)

The policy of the council of the College of Surgeons, in the contemplated legislative changes, was also manifestly to monopolise not only hospital, but also other surgical appointments, for the small proportion of their members to whom they grant the fellowship. To effect this, the fellows of the college were to be highly educated, and their qualifications to practise surgery to be fully and completely tested, whilst the great mass of practitioners were to be educated upon a lower standard, and their qualifications were to be tested for an inferior degree of surgical attainment. Looking at this policy in the most favourable point of view, its object was to create a few great surgeons—the community, not within reach of these great surgeons, being left dependent for surgical assistance upon a class comparatively incompetent. How, the committee beg to inquire, would such a principle of legislation as this affect the limbs and lives of the people of this kingdom? (Hear, hear.)

The medical practitioners of our towns and villages, our collieries, manufactories, and shipping, are not likely to be fellows of the College of Surgeons, so that on the wide ocean and in the recesses of a mine, where the most serious accidents occur, our fellow creatures would be subjected to the practice of those who, although authorised by law to practise as surgeons, are educated to that degree of knowledge only which would qualify them for the treatment of the simplest cases. (Hear, hear, and applause).

Of the premeditated character of these proceedings of the College of Surgeons we have ample proof in the evidence given before Mr. Warburton's committee, and a most forcible illustration in the following fact: Before obtaining the new charter, the standard of qualification by age was reduced from twenty-two to twenty-one years. For many years no individual could present himself at the college for examination until he had attained the full age of twenty-two years; but in the year 1839, when the number of surgical practitioners met all the wants of the community, and was still increasing, then, without any reason, without even a plausible pretext, the council made a bye-law enabling candidates to obtain their diploma at twenty-one years of age. Every one will admit that this curtailment of the period of study by the last and most valuable year, in such a science as that of surgery, was calculated most seriously to damage the respectability of the great body of surgeons, and the council cannot plead ignorance of the tendency of this curtailment, inasmuch as they have made a lengthened period of study an essential requisite for the fellowship. (Hear, hear.) At the period to which the committee now refer, the council also depressed the standard of education and qualification for the membership of the college, by diminishing the period of study from five to four years; and the point which the committee most strenuously insist upon, is this,—that when, subsequently, the council was engaged in the business of medical legislation, for the ostensible purpose of improving the medical profession, they adhered to these pernicious changes—the apparent object of this body being, first, to make the distinction between the general practitioner and the fellow as wide as possible, and then to impose upon the public a numerous body of imperfectly educated licentiates, who were to be legally entitled to practise upon the mass of the population; providing for the wealthier classes and others who could fortunately obtain their assistance the class of fellows possessing a higher degree of professional skill and competency.

It behoves the medical profession to examine the grounds upon which the council of the College of Surgeons have founded this policy. They have attempted to justify it on the broad principle that the general practitioners are both incompetent and unworthy. In particular, they have made, or rather have attempted to make, the dispensing of medicine by the medical and surgical practitioner a badge of degradation. The council have not only made the dispensing of medicine a reason for exclusion from a seat at their board, but

the original intention, as the committee are well advised, was to refuse even the fellowship to every individual who dispensed his own medicines. The committee are well aware that the council, knowing the untenable ground which they occupied, gave up that point to a limited extent in reference to provincial practitioners; and that they also, for the purpose, as it would seem, of making an exception to prove a rule, gave the fellowship to two or three metropolitan practitioners; but the council of the College of Surgeons must give the general practitioners of this country credit for very little discernment, if they believe that the latter can be blind to the real operation of the charter thus carried out; the object is plainly to prevent the general practitioners, particularly those who dispense their own medicines, having any influence in the council; and it has been sagaciously calculated that the franchise may be safely given to a limited number of provincial members of the college, who necessarily dispense their medicines, since of a limited country constituency who must personally attend in London to record their votes, a few individuals at most would do so on any one occasion, and thus, by shutting out the metropolitan general practitioners, the council feel secure that the government of the college will be perpetuated in the persons of the pure surgeons of the London hospitals. (Hear, hear.)

The committee have considered it a duty to inquire most critically how far the conduct of the council, in their attempt to degrade the general practitioners of this country, in consequence of their dispensing their own medicines, is founded in justice and propriety. In the first place, the committee allow that in times past, and to some extent at the present time, certain abuses may have been connected with the practice of the professional man dispensing his own medicines; in the next place they admit that it conduces to the dignity of the profession, and to the welfare of the public, to elevate the character of the profession as far as possible above that of a trading community; that for this purpose, to the utmost that the public will sanction, the general practitioners should cease to be remunerated in proportion to the medicines supplied to their patients; and that they ought in no instance to be allowed to trade in drugs (great applause); and it is further admitted that the profession will be placed altogether on a more honourable footing when that standard of remuneration for medical and surgical services is entirely abolished. On this point the committee affirm, on the part of the general practitioners that in their practice among the more intelligent classes of the community, these evils are being progressively, and they may say of late years rapidly, corrected, and that their correction proceeds *pari passu* with the increased scientific qualifications of the general practitioner and the increased intelligence of the community. (Applause.) But after saying thus much, the committee further affirm, that the mass of the population of this country, from long custom, habit, and, in many respects, from the necessities of the case, as, for instance, throughout the country, in the army and navy, in collieries and mines, and on board ship, must and will continue to employ, as their ordinary medical and surgical attendants, the individuals who dispense their own medicines; accordingly, although many exceptions occur, where, from various circumstances, the general practitioner prescribes, and does not dispense his medicine, the great mass of the profession must continue to dispense. If the general practitioners as a body were to cease to do so, a large proportion of the practice of physic and surgery would go out of the hands of the regular profession, and must necessarily be taken up by the chemists and druggists and other unqualified persons (hear, hear, and applause); and it is most important here to remark, that the principle advocated from the first by Sir James Graham, of throwing open the practice of physic and surgery to any one who might think proper to undertake it, provided only that he does not assume certain specified titles, gave immediate facilities for this change.

Thus, under the title of dispensing chemists, pharmaceutical chemists, or any other title in present usage or newly coined, and not actually prohibited by the Act of Parliament, any individual carrying on the business of a chemist and druggist would have had a legal right to fulfil all the "ordinary exigencies" of the profession, to attend, at the bedside of the patient, either with, or for, the consulting practitioner, and to visit or to prescribe for, and to perform surgical operations upon, the sick at their own homes, without any medical or surgical education whatever, or with such an education, for instance, as under an Act of Parliament for regulating the business of the chemist and druggist, the Pharmaceutical Society might prescribe.

Seeing that the great body of the profession must dispense their own medicines, the question arises whether it is for the advantage of the profession, for the advancement of science, and for the good of the community, that the individuals who do so should collectively constitute a degraded class; whether, in fact, the act of dispensing his own medicine should be a badge of disgrace to the professional man. Surgeons who are members of the council of the college carry their own surgical appliances in their carriages—why should this be considered less degrading to the pure surgeon than the preparation of medicines under his own eye by the surgeon in general practice. As medical science advances, the physical sciences become daily more applicable, and the habit of manipulation becomes more essential. There is nothing, in truth, more degrading in the practice of the various branches of pharmacy by the general practitioners than in many of the ordinary proceedings of consulting practitioners. The whole depends upon conventional usage. The custom of dispensing has been followed from time immemorial by the highest grade of medical men in Scotland, and by more than nine-tenths of the practitioners, metropolitan and provincial, throughout this kingdom, and it is attended with many advantages—the practitioner, for instance, who has to depend in dangerous diseases upon the action on the system of powerful remedies—as mercury, antimony, opium, elaterium, or hydrocyanic acid—will always prescribe with greater confidence when he can secure by his own superintendence the purity of his medicines, and accuracy in compounding them. Moreover, in rural districts, there are no chemists and druggists. The committee feel themselves called upon to ask what is likely to be the immediate effect and the ultimate result of so far degrading the class of medical and surgical practitioners, who must necessarily make manipulation a part and parcel of their education and practice, as not only to depress their standard of qualification, but to deny them a social status, all corporate privileges, and almost every motive of honourable ambition. They believe that legislation in this direction is calculated to inflict a most serious injury upon the profession as a whole, and whilst they admit the existence of certain evils connected with the present system as to dispensing, and whilst they have been striving, and are prepared to continue their efforts, to obtain such an institution as would lead certainly and quickly to the correction of those evils, their most strenuous advice to the general practitioners of this kingdom, in the present state of the law which regulates medical practice is, both on public and professional grounds, neither to allow themselves to be induced to relinquish the dispensing of their own medicines, nor to suffer themselves to be degraded as a class, because they perform that part of the functions appertaining to the practice of medicine and surgery. (Great applause.)

The council of the College of Surgeons have publicly taunted the general practitioners with including among their numbers the puffers and venders of nostrums and secret remedies, individuals who have connected themselves in business with chemists and druggists, retail shopkeepers who expose for sale cattle drugs and perfumery, and persons of notoriously bad character. (Great laughter). The committee of the National Association repel this taunt as manifestly unjust. It is especially the council of the College of Surgeons who have not only tolerated, but, by the laxity of their administration, and in violation of their pledged duty to the public and their own respectable members, have indirectly encouraged those disgraceful abuses. (Hear, hear, and applause.) The council are known to boast of their influence with the government and the legislature; it surely rested with them to obtain powers, if they did not already possess such, to correct these abuses. But the council, in fact, have all along been possessed of sufficient power, and there are strong grounds for the belief that they have intentionally evaded the exercise of it, and have winked at the abuses with which they charge the members of the College (hear, hear), for no other purpose than to associate those abuses with the act of dispensing, and, by imputing them to the whole class, have thereby furnished for themselves an additional excuse for limiting the franchise. (Hear, hear.) The National Association has sought for a representative institution, because with Englishmen representation is regarded as the legitimate source of power, and because, with other objects, they want an institution invested with such powers that the general practitioners may themselves correct the discreditable practices in a liberal profession which have been so long tolerated by the council of the College of Surgeons.

If the council had no other motives than these for restricting the franchise among the general practitioners, the committee deny that there is the slightest rational ground for the limitations they have adopted; but the committee believe that there are other and more weighty reasons—reasons which operate with the government, the legislature, and the College of Physicians, but which the council have thought it expedient to keep back. The original charter of the college constituted it a college of pure surgeons—as the council themselves express it, "for the special cultivation of surgery"—and the council are bound by an oath to maintain it as such. So long as the profession rests satisfied without a representative government, and accordingly without any interference with the internal arrangements of the college, the council assume that they can, consistently with their oath, take cognizance of the general practitioners so far as surgery is concerned; but it is deemed not to be consistent with the constitution of the college to allow those who are more medical than surgical practitioners to interfere with its internal government and arrangements. What the council, in fact, desire is this, not only to prevent the general practitioners having any power or control in the college which they consider they are bound by the constitution of the college to do, but they desire at the same time, in perpetuity, to continue to receive the examination fees of the general practitioner. With these views, their policy has for many years had a uniform tendency to impede the progress of professional improvement in the masses, and to weaken or vitiate their claim to consideration in a legislative point of view.

The committee of the National Association assert that, in common justice and humanity, this policy ought to be put an end to. If, as the committee believe, the College of Surgeons cannot be made the home for general practitioners, and the connexions between the college and the general practitioners can only be sustained by lowering the surgical status and efficiency of nine-tenths of the surgical practitioners in this country, the College of Surgeons ought to relinquish all control over the education and qualifications of the general practitioners; and the committee firmly believe that the college might do this with advantage to its character, as a body devoted to the cultivation of pure surgery, and with immense advantage to the great cause of medical and surgical science.

The College of Surgeons constituted the obstacle to the Apothecaries' Society exercising the power of testing the surgical qualifications of their members, and rendering their curriculum of education and their examinations of the general practitioner complete. The assertion that the general practitioners voluntarily seek the membership of the college is not strictly correct. The truth is that, although the license to practise held by the gener[al] practitioner enables him without illegality [to] practise every branch of the profession of me[di]cine, and indeed is the only compulsory legal [title] to practise, no general practitioner can fill [the] office of surgeon in a public institution wi[thout]

some specific testimonial of his qualifications to practise surgery, and his legal certificate of qualification from the Society of Apothecaries not specifying surgery is in this respect incomplete. Accordingly, in the absence of a complete curriculum of education, upon the broad principle that medicine and surgery are one science, with a comprehensive and satisfactory test of competency by examinations on the same principle, every young man who has his way to make in the world, and is not willing to undertake the duties of general practice at a great disadvantage, is *compelled* to seek the certificate of the College of Surgeons, howeveer imperfect the curriculum of educaton may be, and however inadequate the test of qualification, since the College of Surgeons is the only source from which a certificate in surgery can at present be obtained. (Great applause.)

The committee have entered into these details at the risk of proving tedious, because they considered it necessary, in order to obtain a thorough understanding of the question which has arisen, whether it is practicable or feasible in any wise to alter the College of Surgeons so as to convert it into the institution which is required as an alma mater for the general practitioners in medicine, surgery, and midwifery, of this country; and they now proceed to re-state what, after all their discussions, deliberations, and negociations, they still believe to be the legitimate objects sought for by the general practitioners.

In the first place, the general practitioners claim a representative institution with an elective council, possessed of authority to frame bye-laws, whereby they would be enabled to check all improper practices of their members—whereby they might give a proper direction to the principles upon which professional practice ought to be conducted—whereby they might settle, as the committee believe, most amicably, the disputed questions between the qualified practitioner and the chemist and druggist—and whereby they would effect numerous ameliorations and improvements in the medical profession, so as to establish it on the basis of true respectability in the eyes of the public and of the whole world. (Great applause.)

Secondly,—They claim the unfettered power of determining a curriculum of education, including all that is requisite both in a general and scientific point of view, to secure a sufficient guarrantee of competency in every individual who is to enter into general practice, and the unfettered power of selecting a Court of Examiners and of instituting such examinations as will prove a satisfactory test of such competency. These objects are only to be effected by a charter of incorporation and an Act of Parliament to support that charter; and would be obtained by the concurrence and co-operation of the Society of Apothecaries with the general practitioners, in conformity with the liberal policy of that society in disclaiming any corporate or particular interest while advocating the claims of the general practitioners to a separate and independent incorporation (Applause). The expression by the Society of Apothecaries of "their readiness and willingness, irrespectively of personal and corporate considerations, to resign all further interference with the education or control over the affairs of the general practitioners, and to assist in obtaining the grant of such independent charter of incorporation as would secure to the general practitioners an efficient control over the education and examination of their own class through the machinery of the organisation of the members of that class," indicates the liberal views entertained by the society.

Thirdly,—Although, in the course of the recent negotiations, the committee waived the point of a summary penal enactment, the Right Hon. Sir James Graham having stated his determination not to make restriction on the practise of physic and surgery by unqualified persons a part of his measure, and a majority of the committee's constituents having expressed their desire to accept with gratitude the proposed legislation of the Right Honourable Baronet—and although in the bills introduced into Parliament the indirect checks were of considerable importance, and in the two atter of these bills the joint deputation succeeded in inducing the Government to preserve the existing penal clause, yet the committee are perfectly convinced that these intended safeguards to the public were incomplete and insufficient, and that the claim by the medical profession on public grounds for a summary penal clause has a foundation in justice and sound policy; and they consider that all classes of practitioners ought to fall back upon this claim as one of the essential elements of medical reform with a view to any future legislation. (Great applause.)

The government having abandoned medical legislation, at least for the present, the field is, of course, open; and it becomes a serious question what steps the general practitioners ought, at the present moment, to take. The committee are of opinion with the joint deputation, as expressed in the preface to their published reports, that matters should not and cannot be allowed to remain stationary. They consider that the general practitioners ought to maintain their organisation, with an authoritative council at all times prepared to act for them, should any future attempts be made by other parties in the matter of legislation; and invested with power, also, on the part of the general practitioners, to take, without a moment's delay, such active measures in furtherance of their objects as in their judgment may be calculated sooner or later to bring the long-continued exertions of the medical profession to a successful issue. (Applause.)

But the committee regret to say that they do not at present see a prospect before them of this question being speedily brought to an issue, so as to justify them in recommending the National Association to continue its present ephemeral mode of existence. The Association has now a committee consisting of one hundred individuals, who have acted in the immediate vicinity of the seat of government as a kind of convention; they were appointed for the purpose of coping with the emergency created by an immediately impending legislative aggression, and the footing upon which they were placed, was the most judicious possible for this particular purpose. But the committee feel bound to state their conviction that if the general practitioners are to continue their organisation with any chance of permanency for the purpose of protecting their own and the public interests, and of ultimately obtaining their legitimate objects, they must place the Association upon a broader and a more substantial basis (great applause); and with this view the committee recommend to the meeting the establishment by the National Association, originally formed for the attainment of certain specific objects, of a NATIONAL INSTITUTE OF MEDICINE, SURGERY, AND MIDWIFERY (protracted applause), for the purpose of comprehending a much wider range of social and professional advantages.

The meeting will naturally desire to be made acquainted with the immediate advantages which would accrue to the general practitioner as well as the more remote objects which would be aimed at by the establishment of a National Institute of Medicine, Surgery, and Midwifery, on such a basis, and the committee will endeavour on these points to explain their views as concisely as possible.

In the first place, they contemplate that the NATIONAL INSTITUTE should be governed by a representative council composed both of provincial and metropolitan members, and should be organised with local secretaries and branch associations in every Parliamentary district in the kingdom, after the plan of the National Association. The first duty of this representative council would be vigilantly to watch the course of affairs, so that in the event of any new attempt at legislation they would be prepared at once to advise the profession of its bearings, and to take such steps as the interests of the body they represent or the public interests might require. The committee will illustrate the importance of such a representative council to the general practitioners of this country, by reference not only to the recent attempt at direct legislation, but also by referring to several other measures affecting the medical profession, which have been, or are likely to be, brought before Parliament. There is at present before the legislature, besides the Poor-law Amendment Bill, which contains clauses of it is intended to appoint commissioners who are to take upon themselves the direction and control of charity affairs. During the last session a bill was prepared and brought into the House of Commons by the Earl of Lincoln and Sir James Graham, intituled the *Sewerage and Drainage, &c., of Town's Bill*, in which Bill the appointment by commissioners, under the approval of the Secretary of State, of a class of functionaries hitherto unknown in this country, with the title of "Medical Officers of Health," was contemplated for every town and district throughout the provinces, and there can be no doubt that an Act of Parliament of this nature must be sooner or later passed. It would become the duty of a representative council to look well to the provisions of such Bills as these, and to see that the appointments are not made subservient to class interests, or a monopoly for the junior fellows of any particular college. (Hear, hear, and great applause.)

No person can be blind to the fact that social changes are now in progress which must most materially affect the medical profession, and in particular the general practitioners; and the committee seriously inquire whether the interests of the general practitioners are any longer safe in the present state of things. The College of Physicians will take care of the interests of their own members; the council of the College of Surgeons will doubtless take care of the interests of the fellows; as to their members, it is now written in the pages of the history of the college, that except so far as the examination fees tend to the support of the college, it is comparatively indifferent to their interests. (Protracted applause.) Where then is the conservative power of the general practitioners' interests? Of the interests of nine-tenths of the medical practitioners of this country, who have no corporate provision—no representation—no home of their own. Or, to put the question in a broader light, where is there a power reposed to protect the public interests — the interests of every individual in this community, from the Queen to the humblest of her subjects, who, is liable to be thrown upon the judgment and skill of the general practitioners in medicine, surgery, and midwifery? The Apothecaries' Society has done, and will continue to do, its best; but the limitation of its powers is an effectual barrier to its efficiency; the great body of the profession has no authoritative head to depend upon, and the committee hold that it is imperatively called upon, both on public and professional grounds, to place on a permanent basis a collective organisation, with as much power and authority to perform the various functions required, as the profession by numbers, respectability, talent, and adequate funds can give. The committee of the National Association has acted to the best of its ability throughout the trying circumstances of the last eighteen months—it remains for the profession to judge with what advantage—but the profession undoubtedly requires that a representative executive should be established, for the purpose not only of continuing the functions of the committee, but of effecting many other important objects which were not originally contemplated, or which, rather, have been placed in abeyance by the promise made to the general practitioners of the immediate grant of a charter of incorporation, with an Act of Parliament to carry out its provisions.

Secondly,—The representative council of such an institution would be a protective body; they would be enabled to perform many duties, the object of which would be to protect the interests of the legally qualified practitioner, and of the public. Among other important duties which might be imposed upon them, is that of publishing annually, in the absence of any legal registration, a registry of the qualified practitioners in actual practice, and thereby of virtually exposing the pretensions and practices of unqualified persons; and in this respect they would give facilities to the exercise of the power vested in the hands of the Society of Apothecaries, of prosecuting those

who render themselves amenable to the law. (Hear, hear, applause.)

Thirdly,—This representative council, possessed of the confidence of the profession, would have it in their power not only to encourage the Apothecaries' Society to prosecute their duties with increased zeal, and to continue to elevate rather than depress the character of their examinations, but it would also be incumbent on them to watch vigilantly the curriculum of education for the member of the College of Surgeons—the individual who is afterwards to become a general practitioner—and if the standard of qualification for the membership should be insufficient to secure his efficiency to practice surgery as a general practitioner, to appeal from time to time for redress of this or any similar grievances from the legislature.

Fourthly,—A National Institute of Medicine, Surgery, and Midwifery, if undertaken with spirit and properly supported, would have it in their power to publish "Transactions" periodically. These Transactions would comprise all that is going on in the profession, political and scientific, essential to be brought immediately home to the doors of the general practitioners; and they would be a means of internal communication between the central council, the honorary local secretaries, and the members of the branch associations, which must prove of incalculable utility to the profession at large.

Fifthly,—The National Institute might immediately commence the formation of a library. It is quite true that at the present moment there are several very valuable public libraries, but not one of these is placed upon a footing which renders it eminently serviceable to the general practitioner. The library of the College of Surgeons can only be resorted to by personal attendance at the College; but it is totally impracticable for the general practitioner in actual practice to leave his home for literary pursuits. The library of the Medical and Chirurgical Society is conducted upon the most liberal plan, but this society only admits a certain proportion of general practitioners; and altogether there can be no question, considering the great increase of numbers in the medical profession, and the daily increasing facilities of transmission, that the general practitioners might commence the establishment of a library for general use and circulation, which would ultimately prove of inestimable advantage to themselves and their successors. (Hear, hear.)

Sixthly,—If a National Institute of General Practitioners in Medicine, Surgery, and Midwifery, were to commence the formation of a museum, there can be no doubt that a collection of the most valuable kind would be rapidly made; one gentleman has stated that he should be prepared to deposit at once, as a nucleus, a collection by his own hands of 3,000 specimens in natural history. Other gentlemen have lamented that there is no institution which they can call their own, in which might be deposited collections and isolated specimens. The labours of the general practitioners in the metropolis and throughout the provinces, and their extensive resources, are rendered unavailing and nugatory in the cause of medical and general science, just in proportion as they are deprived of encouragement by exclusion from that position in the profession which they claim, and to which they are so justly entitled; and if their energies were enlisted by engaging as a body in such an institution, voluntary or otherwise, there can be no doubt that medical and surgical science would immediately receive a very great impetus.

Seventhly,—A National Institute might at once establish prize essays and examinations on specific subjects to be conducted in public, which must conduce to the advancement of medical science. The Institute would also promote the friendly communication of its members with each other—tend to destroy those jealousies which have too frequently exhibited themselves in the present dissociated state of the profession, and would lead to the establishment of a well understood, consistent, and liberal although not fastidious, code of medical etiquette—essential not only for the honour and comfort of the profession, but for the safety and welfare of the sick.

Eighthly,—If the members of the profession, practising on the broad principle that medicine and surgery are one science, were thus to form themselves into a National Institute of Medicine, Surgery, and Midwifery, it would constitute the frame work of a corporate body, ready prepared, should the Right Honourable the Secretary of State change his present intention on the subject of medical legislation; and redeem his original pledge; and it would be the duty of the council to use every legitimate means to urge from time to time upon the legislature and the Government their claims for a charter of incorporation, and for such an Act of Parliament as would secure to the public a high standard of qualification for every individual who is allowed by law to practise medicine and surgery, and to the profession at large those rights and privileges which they have so long contended for.

These are a part only of the advantages, as appears to the committee, which would accrue to the general practitioners by forming themselves into a permanent collective body; and in throwing out this suggestion to the meeting, the committee cannot do better than to quote a part of the 30th and the 31st clauses of the "Manifesto" issued by the Medical and Surgical Association of the Borough of Marylebone, a few weeks before the National Association came into existence.

Clause 30.—"The position of the general practitioners of this country is at present most anomalous. They are acknowledged as practitioners of medicine alone, under the Apothecaries' Act. They have hitherto been recognised as practitioners of surgery alone, by the College of Surgeons; neither the Apothecaries' Company nor the College of Surgeons know them as general practitioners of medicine and surgery. Although an indispensable professional body, numbering perhaps fifteen or eighteen thousand, possessed of incalculable individual influence, they are unknown as a collective body." (Hear, hear.)

Clause 31.—"The first step towards procuring a prompt and efficient remedy for the evils that afflict this large and important class in the profession, the anomaly of position, the defects in education,—the want of defined privileges and protection, is unquestionably for the great body of general practitioners in the kingdom to combine and to form a society of their own."

The committee do not bring a scheme of this magnitude and importance under the notice of the meeting without having well considered the difficulties which surround such an undertaking. They are fully aware that if the meeting should hail it enthusiastically, and in the most cordial spirit determine unanimously at once to invest a committee with power to carry it into effect, its success must still be problematical. For the purpose of carrying out all the above objects, a very large annual sum would be required; yet, if from five to ten thousand general practitioners were to act so far in concert as to subscribe a small sum each annually, a very large yearly income would be derived; and the committee are so convinced of the innumerable advantages which would accrue to the profession by thus combining together under a representative institution, that they have felt that they should not do their duty if they omitted at this juncture, thus publicly, and thus forcibly, to place the matter before the meeting.

The committee beg it may be understood that they do not recommend any speculative proceeding. The utmost they can advise is, that if the meeting concur with them in their views, they should resolve that it is expedient to form the National Institute, and that they should invest a body of individuals, in whose judgment and discretion they can place reliance, with power to make the effort; nor do they wish it to be understood that they expect an institute in all its departments and ramifications could be accomplished at once—it must be a work of time. They apprehend the proper course would be to employ the machinery of the National Association for the purpose of canvassing the members and the profession generally, by circular letters, to ascertain whether they are desirous of entering into such an undertaking. If they are not disposed to do so with zeal, and even with enthusiasm, or by some other means to maintain an effective organisation, all amelioration of the condition of the general practitioners is hopeless. It would be unreasonable to expect that a few individuals could give the time and attention required, and subject themselves, even in a great public cause, to the anxieties and responsibilities which must necessarily be engendered, unless they receive the encouragement and assistance of a very numerous body of the profession.

An indispensable requisite to the permanent establishment and efficient working of such an institution, is undoubtedly that the utmost confidence should be reposed in its executive council, and particularly in those upon whom the duty may be imposed of carrying the wishes of the profession into effect in the first instance. If the constituency cannot accord this—if the medical profession is of so jealous a character that it can repose confidence no where—if, during the discussion of the most serious negociations and the transaction of the most important business, parties inimical to the interests of the institution are to be present in the council-room, public meetings to be clamorously called for, and an exposition to the public of the state of business, before that business is complete, is to be pertinaciously demanded—if, in the executive council, where the interchange of opinion should be free as air, gentlemen are to be over-awed by misrepresentations of their acts and motives (applause, protracted during several minutes), the committee state that the establishment of an institution of any permanency or importance is totally impracticable. The committee are fully aware that the profession has great cause for suspicion arising out of the manner in which it has been treated by self-elected councils; but it should be borne in mind that an institution in the medical profession on a liberal representative principle, would be placed under far different circumstances, and that there must then be a day of account for the executive, whatever its conduct may be.

After the most patient deliberation and re-discussion of every point, it is the opinion of the committee that the NATIONAL INSTITUTE should be founded on the basis of the "Heads of Charter" already sanctioned by the Association, viz.,

As respects qualification for membership, that it should embrace, in the first instance,

"Gentlemen who were in actual practice previous to the 1st of August, A.D. 1815.

Licentiates of the Society of Apothecaries.

Members of the Royal College of Surgeons in England, Ireland, and Scotland.

Doctors or Bachelors in Medicine of any university of the United Kingdom, and Fellows or Licentiates of any College of Physicians of the United Kingdom who shall have been in actual practice as general practitioners in medicine, surgery, and midwifery, or who shall satisfy the council of their qualifications to practise in medicine, surgery, and midwifery, and who are at present Members of the National Association, or who shall enrol themselves previously to the expiration of six months from the date of the formation of the Institute."

Subsequently—

"Such persons only as shall satisfy the council as to their qualification to practise in medicine, surgery, and midwifery."

That its government should be—

One president, "to be elected by the council triennially, and eligible for re-election."

Three vice-presidents, to be elected by the council from their own body by ballot, one to go out every year, and not to be eligible for re-election for a year.

A council, "to be composed of forty-eight members, one half practitioners resident within ten miles of the General Post-office, the other half country practitioners resident beyond that distance. No member of the Institute to be eligible as a member of council under —— years from the date of his qualification to practise.

"The council to be elected by the members of the Institute; every enrolled member to be entitled to a vote.

"One-third of each metropolitan and provincial branch of the council to go out of office annually, and the vacancies to be filled up in equal proportions from the respective branches, but the retiring members not to be eligible for re-election for a year.

"The election to be by voting papers, and decided by a majority of votes.

"The council to prepare a code of laws for the regulation of the affairs of the Institute, subject to the approval of a general meeting of the members."

In drawing up the present report no attempt has been made to embrace the whole case of the General Practitioners. The committee believe, however, that the claims of the profession as respects general practice must be laid completely before the public; that the proper place to do this efficiently is the floor of the House of Commons, and that the appropriate time is approaching. The committee cannot conclude without alluding to an additional injustice towards the general practitioners recently attempted in the "Hunterian Oration" at the Royal College of Surgeons (applause), and, although the past history of that body might lead them to evince little surprise at any step taken by the council of the college for their own exaltation, the committee were, nevertheless, scarcely prepared for the wanton and unjust accusations which the individual who delivered that oration thought fit to bring against his professional brethren. The attack was sure to produce fresh agitation in the minds even of the most peaceable. It was unjust, because, both in precise and general terms, the orator imputed to the general practitioner—his co-equal in rank, by virtue of his examination—(Great applause)—an inferiority of attainments; omitting what is due to the members of the college and to the great mass of the profession, with all that is essential to put the merits of the medical question fairly before his hearers. The oration was calculated to mystify the public still further upon the subject of medical politics, and the presence of a large assembly of influential members of the community (not of the profession) was selected as a fit occasion to promulgate the libels which it contained—(applause)—perhaps in the hope that what the cause wanted in truth and justice might be supplied by violence and harshness of language, tone, and manner. In the many difficulties which have beset the committee in the discharge of their complicated duties, it has been their endeavour, as as well as their desire, even under circumstances of great provocation, to express themselves mildly towards their opponents; the circumstances, however, to which they now refer are such, that, as the representatives of a great proportion of the profession, as well as in their own persons, they feel that they would depart from their duty if they did not, in the strongest and most unequivocal language, express their disgust at the attempt made upon the occasion alluded to, to mislead the public upon the subject of medical competency, to degrade the qualified practitioner, and seriously to impede the progress of medical education. (Applause.) Without dwelling further upon this topic, the committee will conclude by remarking that, as respects the consulting surgeons, a large portion of their practice is of a medical character—(applause)—for which their professional education by no means necessarily qualifies them; the committee therefore trust that, upon an improved organisation being effected, some early means may be taken to secure such a test of fitness on the part of all persons who practise medicine as will afford adequate protection to the public.

The National Association numbers upwards of 4,000 members, and the committee are justified in stating, that it has exhibited of late, if possible, a greater unanimity of sentiment, and a more consistent firmness of purpose, than at any former period (Great applause). As a great professional body the association has taken its stand in the cause of MEDICAL REFORM. The essence of that reform lies in a high standard of education and qualification for every medical practitioner, an improved social status of the whole profession, and protection to the public against unqualified pretenders. In the theatre of the College of Surgeons, names, great in the annals of surgery, have been invoked to vindicate an illiberal policy, but the profession can appeal to its Cheseldens and Hunters in spite of the College of Surgeons of England. Ages of barbarism could boast of the distinguished names, and, at all periods, the most brilliant examples of human genius have burst through the clouds of ignorance with which they have been surrounded. A characteristic of the present age is the general diffusion of knowledge, and no stroke of policy by interested colleges, nor any efforts of hostile councils, can now be allowed to stem the onward progress of professional knowledge. (Applause.) It has been gravely asserted that, by educating the general practitioner highly in medical and surgical assistance would be thereby rendered *too costly* for the poor, but this is to make learning and science the parents of extortion and inhumanity, which common sense denies; and experience may be appealed to in proof that the better informed and the more competent the members of our profession, the more willingly, considerately, and effectively are their knowledge and skill bestowed upon their necessitous and unfortunate fellow creatures. (Great applause.) The cause in which we are engaged is not that of the rich only, whose wealth can command the assistance of the most eminent men, but it is the cause of the poor and needy, whose daily bread depends upon their health, and who must rely in sickness upon the aid which is nearest at hand and most readily available. It is not the cause of the highly educated portions of the community only, who might be allowed, without charging the law with inhumanity, to choose for themselves between the professor of true knowledge and experience and the arrogant pretender, to whom, perchance, the pleasure may be as great

"of being cheated as to cheat"

but it is the cause also of the vast majority of the community who have no means of judging correctly in matters which they cannot understand—of the helpless infant, whose anxious mother would place its life at the disposal of those who make the highest pretensions—of the female part of the community, who would fall into the hands of boasting charlatans in the most critical moments of their existence, when ignorance may engender rashness, and rashness lead to death. The cause in which we are engaged is that of medical science, and the great medical and surgical interests of this community, and there can be no reason to doubt that, at a period not far distant, a paternal government and a wise legislature will see the humanity, justice, and sound policy of placing the medical profession of this country upon a more consistent, a more substantial, and a greatly improved basis.

The committee having now made their report, and having laid before the meeting their suggestions and plans for consideration, respectfully place themselves at the disposal of the members at large. (Immense and protracted applause.)

Mr. PURCELL, of Winchester, said that he had much pleasure in proposing the adoption of the first resolution; he begged to express, on the part of the medical practitioners in the neighbourhood in which he resided, the perfect confidence which they felt in the committee of the Association. The resolution was as follows:—

"That the report just read be received, entered upon the minutes, and forthwith printed, and that the thanks of this meeting be cordially given to the committee for the zeal, intelligence, and discretion displayed by them in advocating the claims of the general practitioners, and also for the able and consistent manner in which they have endeavoured to carry out the objects of the National Association."

Mr. LIDDLE seconded the resolution, which, he was sure, was one in which all would cordially unite. There could not be any difference of opinion on the subject. They were all deeply indebted to the committee for the pains they had taken, the time they had bestowed, and the talent they had displayed, in all their transactions, and more especially in the very able report which had just been read. He (Mr. Liddle), as a member of the Tower Hamlets Medical Association, was able to bear testimony to the great urbanity shown by the committee on all occasions, and the readiness which they equally displayed to meet all difficulties and differences of opinion in an amicable spirit. (Applause.) At present there is not any medical bill before Parliament; they now start anew, but with this great advantage, that they are already an organised body. He (Mr. Liddle) trusted that all differences of opinion on these matters would cease, and that they would centre their exertions in one common object—that of establishing the National Institute of Medicine, Surgery, and Midwifery. In conclusion, he cordially seconded the resolution.

The resolution was then put, and carried unanimously.

Mr. BEDINGFIELD, of Stowmarket, observed that, when he entered the room, he had not any intention of taking part in the discussion; he had intended to be merely one of the auditors. He had, however, been requested to propose the second resolution, which he had great pleasure in doing. He himself was principally known as having written formerly in the journals on the question of medical reform—a subject he had been induced to take up from noticing the defective condition of the College of Surgeons. He then stated that in early life he had purposed obtaining the college diploma, with the view of entering the medical service of the army, but was deterred by his friends, who pointed out that the diploma of the college was of so little estimation, that the government were not content therewith, but required all candidates for their medical services to pass a second examination before they could obtain commissions. He then settled in the country without the college diploma, and at that time it was estimated so slightly, that four out of five of the surgeons to the Bristol Infirmary were in practice without it, and he believed that two of the surgeons to that institution at the present time were not members of the college. He (Mr. Bedingfield) believed that it was no disgrace not to belong to the college, and whatever merit might have attached to the possession of its diploma had been destroyed by the recent acts of the college council, and by the late charter. He thought that the additional examination for the fellowship was a libel on the profession, which the general practitioner would properly resent by separating altogether from the college, and establishing the proposed National Institute. The advantages that would be derived from the founding the Institute had been so ably detailed in the report, as not to require any comment from him. He regretted much that it was not in existence prior to the passing of the poor-law bill, in which case the advantage that had been taken of medical men would never have been attempted; there was at this moment a scheme on foot for the further degradation of the profession; he alluded to the proposal that government should pay a part of the salaries of the union medical officers, and thus render those gentlemen servants of the crown, and deprive them of their elective franchise and privileges as Englishmen. (Disapprobation.) Mr. Bedingfield concluded by proposing the second resolution, which was:—

That the indefinite postponement of the settlement of the medical question in Parliament, and the consequently unsuccessful issue of the exertions of the committee to obtain a charter of incorporation for the general practitioners, is chiefly to be attributed to the existing colleges having unduly exercised their influence, and thrown unwarrantable obstacles in the way of the Secretary of State for the Home Department; that in consequence an absolute necessity exists for the general practitioners to maintain a permanent collective organisation, with an authoritative council to protect their interests; it is, therefore, the opinion of this meeting that the recommendation of the committee in the report which has just been read, that the National Association should be established on a more permanent basis, be *forthwith adopted*, and that the members of the Association, and of the profession generally, be canvassed as to their willingness to co-operate in the formation of a 'NATIONAL INSTITUTE OF MEDICINE, SURGERY, AND MIDWIFERY,' on the plan recommended in the report.'

Mr. Bonney, of Brentford, in seconding the resolution, described the necessity of forming the National Institute as much to be deplored, inasmuch as it resulted from the grievances under which the members of the profession laboured, one of the principal being that they had no participation in the management of their own college. The same injustice obtained in the College of Surgeons, in Edinburgh, of which he was a licentiate. The licentiates of that college did not participate in any way in the management of its affairs. Another grievance was that there was not a full and complete examination for gentlemen about to engage in general practice. There was not any examination in midwifery, and if the new institute contemplated nothing more than midwifery, still it would be a great boon to the profession, and consequently to the world at large. But it would be far more than this—far more even than its founders imagine—it will be a measure of peace—because it would be a measure of power —of that readiness to wage war, which is ever the surest safe guard of peace. The arrangements proposed for the exercise of the elective franchise constituted, in his opinion, the nearest approach to universal suffrage that could be conceived, while at the same time it was free from the dangers attendant on political elections, inasmuch as the members of the medical profession were not a mob, but gentlemen of education, not liable to be misled by a factious demagogue—like sheep following the lead of a ram with a bell fastened to his neck. Even those individuals, belonging to the other college, who now stand aloof, would ultimately see that there will be a place in this college which even they might fill with honour to themselves, and he (Mr. Bonney) would be always willing to leave the seats of honour at their board for those gentlemen, if they were willing to occupy them. He (Mr. Bonney) was inclined to look upon this Institute as the nucleus of a National faculty of medicine, in which all qualified practitioners would be registered; and in that case he would wish that none should be afterwards admitted, who could not prove by actual examination that they possessed a thorough aquaintance with all the branches of the profession, every one, however, being at liberty afterwards to practice solely any one particular branch or subdivision of the healing art, which he might feel inclined to direct his attention to. Mr. Bonney then seconded the resolution, which was put, and carried.

Mr. Daniell, of Newport-Pagnell, remarked, that the observations he was about to make in proposing the third resolution, would refer to the provincial members of the association, and not to the metropolitan. He should give his full support to this resolution* for the present maintaining the National Association, as without it the general practitioner would not have a home,—which was certainly not to be found in either the College of Physicians or Surgeons. The National Association is the only institution that could be a home for the general practitioner; that is, providing it met with the support it deserves. (Applause.) There were points constantly occurring in the course of practice, which required that there should be some body for general appeal. For instance, the management of the new poor-law, as regarded medical practitioners; it was lamentable to notice the way in which they were degraded by it. When he (Mr. Daniell) first entered into practice, he had medical charge of five parishes under the old poor-law, at a salary of £100 a year, and he now, under the new system, attended the very same district for £25 a year. It might be asked why he did not give up the parishes; but if he were to do so, there would be others ready enough to take them; and an old-established practitioner did not like to see others riding over the very circuit that he had himself made. If he abandoned the union practice, he would often find his private practice cut up by his successor in the parish surgeoncy. Some means are wanting by which the commissioners of the poor-law may be taught they must not oppress the general practitioner. Mr. Daniell then gave a description of an interview he had had with the income-tax collector, the latter being desirous to surcharge him. On showing the collector his drug-bill, the collector remarked, "why, Sir, a horse doctor would make more of his drugs than you do." "Very true," was the reply, "a horse-doctor is infinitely to be preferred to an union doctor; and the farmers think a great deal more of their cattle than they do of the poor, or even of their own lives, for they pay the bill of the veterinary surgeon with great readiness, recollecting that he has saved the life of a valuable animal, but when their own bill comes in, then it is, "Why, doctor, how heavily you charge." (Laughter.) These are standing truths, and not to be questioned; he (Mr. Daniell) knew them from experience. The National Association, then, should be maintained in full vigor, that it may be a home for the general practitioner, and a medium by which his grievances may be redressed. He (Mr. Daniell) was very solicitous that the National Institute should be established, as he felt convinced that it would be one of great importance and value to the medical practitioner; and he trusted that every member of the profession in the kingdom would unite to give it his support.

Mr. Rogerson, of Liverpool, had much pleasure in seconding the resolution just proposed by Mr. Daniell. He placed great confidence in the committee of the association, and alleged as his reason for doing so, the able conduct which they had evinced in their past transactions. In the management of the affairs of the association they had shown great firmness, tempered with the spirit of conciliation. They were now unfettered by the chains of Government, and rested entirely on the support of the profession, to which he thought they were fully entitled.

Mr. Sparkes said that before the resolution was put he wished to ask a few questions, and offer some suggestions. He had listened to the report with unmixed and unqualified pleasure. He referred to the proceedings of the College of Surgeons at this epoch as being fearful in their consequences, if they were not stemmed by such a barrier—such a bulwark as the National Association. During the whole progress of these proceedings, there had been—he would not say an invidious opposition, but great discrepancy of opinion, and not a few persons looked upon the proceedings of the Association with suspicion, their object being professedly to rally round the College of Surgeons, and make it by suitable reform the alma mater of the general practitioner. Associations had been formed in various parts of the country with that object in view, and he (Mr. Sparkes) thought it would be advantageous to come to terms of reconciliation with those bodies. He wished to see the general practitioners united in one brotherly band of concord, with the sole object of advancing their real interests, and he thought that this might still be attained. Their great object should be to merge all the associations in one great Institute of Medicine, Surgery, and Midwifery, the formation of which was recognised in the first resolution, with which, however, he thought the second resolution did not comport. The continuance of the committee of the Association was not compatible with the formation of the Institute; he would not attempt to disparage their services in the least, but still he would prefer that there should be formed that evening the provisional committee of the National Institute, and that the gentlemen constituting the committee of the National Association should be appointed the members of this provisional committee. If they all combined together, they might yet induce the Secretary of State again to take up the subject, and provide them with a proper home by legislative enactment. He did not like to propose an amendment; he was quite satisfied with the principles of the resolution, but he should prefer the appointment at once of the provisional committee.

Dr. Webster, of Dulwich, explained that the meaning of the resolution was, that the committee should continue for a short time, and then merge into the National Institute. The next resolution exactly embraced the views advanced by Mr. Sparkes. He (Dr. Webster) congratulated the meeting on the character of the report, which was of such a nature as to afford unqualified satisfaction. The proposed institute is on a scale of the greatest liberality. The throwing open the College of Surgeons to the general practitioner was a step that would not be taken during the life-time of the present race of medical men, and latterly even greater degradation and insult had been heaped upon them, because they were taking steps to obtain medical reform. He (Dr. Webster) saw many of the associated surgeons around him, and he knew that the committee of the association would be happy to unite with them. He thought it was doing an injury to the profession to assume that the College of Surgeons could ever be made the home of the general practitioner; they would always be regarded there as a degraded class. He concluded by stating that a deputation from the associated surgeons had been received by the national committee, on the subject of amalgamation, and he believed that the same spirit now animated the other associations.

Mr. Bowker remarked that he kept a shop, and was not aware that he was in any way degraded by so doing. He had acquired in that way an amount of professional knowledge, which no hospital attendance could ever have afforded. If this association were to fail, where should he and such as he, look for protection and sympathy. He could not find it any where, but was held forth as degraded and wanting in the requisite mental qualifications, although probably as deeply read in nature's book as those who take a higher rank. He concluded by speaking highly in favour of the committee, and saying he would afford it his utmost support.

The resolution was then put from the chair, and carried—

Mr. Woolridge, of Southampton, in proposing the fourth resolution, said he had every reason for claiming the indulgence of the meeting. He must, however, detain them while he said a few words on the resolution entrusted to him. He would first read the resolution.

Resolved "That the committee of the National Association be requested to continue their functions for the purpose of carrying out the two last resolutions, and that a future public meeting be called, as soon as the committee may be prepared, to receive a report from the committee of their proceedings, and of the opinions of the profession on the formation of a National Institute of Medicine, Surgery, and Midwifery." Some gentlemen at Southampton objected to the name of general practitioner, and on their behalf, knowing as he did their feelings on the matter, he hailed with pleasure the alteration in the name of the proposed institution. On Wednesday evening last they met in full number, and passed a resolution to the effect that they would assist the committee of the National Association to the utmost in carrying out their views; and at that meeting also they subscribed liberally to aid the Association. His friends at Southampton thought, however, that the surgeons should either be restricted to surgical practice alone, or be compelled to undergo a medical examination. At present he believed there was no difference between the practice of a London physician and that of a London surgeon; the latter attended medical cases as much as the former. Much had been said by different parties about dispensing being degrading to the general practitioner. The idea was ridiculous. Medical men in villages must send out their own medicines, and he believed that even in London many of the purest gave physic.

Mr. Miles Beale, was a member of the city of London Association, and as such, would give his most cordial support to the resolution on their behalf. He was quite sure that the members of the City Association would most cordially rejoice

* "That it is expedient that the National Association should maintain its present position, that it may be prepared to act in any emergency that may arise, and be ready to avail itself of every suitable occasion to urge upon the legislature the pressing necessity, on public grounds, of a revision of the laws affecting the medical profession; and also as a numerous and important collective body, that it may exercise all the means at its disposal to produce a satisfactory settlement of the complicated question of medical reform."

in the continuance of the committee of the National Association; they would feel that it was the means to the attainment of the great end in view—the National Institute of Medicine.

Mr. Cooper, before the resolution was put from the chair, wished to say a few words. He must remark that most unfortunate dissensions had existed, and still did exist among the members of the medical profession. He thought that steps might be taken to arrange these differences, and he had no doubt that by a little forbearance on the one side and a little forgiveness on the other, everything might yet be satisfactorily arranged. The profession had need of all available support, and in an emergency like the present should act as one man. He thought that if the resolution could be altered a little, as Mr. Sparkes had suggested, by the alterating their title to that of "provisional committee with power to add to their number," much in the way of conciliation might be effected.

Mr. Clifton was so fully convinced that these sentiments animated the committee, that they would instantly adopt the suggestion.

Mr. Sparkes expected to have seen a gentleman present, who was known to the profession more "as a critic than as a practitioner." That gentleman must feel the necessity of conciliation. (Cries of "he is present," "Wakley," "Wakley." "No, no, no," and "hisses.") He was satisfied that if the alteration which had been suggested, and which was agreed to by the gentleman who had just spoken, were carried into effect, much of the difficulty of conciliation would be removed.

Mr. Clifton thought his friend had entirely mistaken the question; this committee was only constituted in order to take into consideration the sentiments of the profession: and it had been always intended that the profession should choose their own council to conduct the affairs of the Institute. It was, therefore, not as any compromise for the future, but merely to obtain the sentiments of the profession, that the committee had consented to the proposed arrangements.

Mr. Wooldridge wished to make a few observations respecting forbearance. The committee had shown abundance of forbearance, and he thought they should proceed at once to business. He was prepared, together with his colleagues, to support the Association with purse and person. He thought that all conciliation and forbearance should come from the other side.

Mr. Davis, of Hampstead, thought that for the Association to forbear after all the insult and injury heaped on them would be only to expose themselves to further scorn and obloquy. They had been members of the College of Surgeons, and they were deprived of their standing and rank in society by the self elevation of their equals into superiors. They had been called geese—for his part he had been a goose to be plucked by that very man, and that man the son of a respectable general practitioner. He (Mr. Davis) had known his father well, and he had known Mr. Lawrence, too, when he was his father's dispensing assistant. What had raised the gentlemen of the council so high, that they should turn round on their former equals, and tell them so disdainfully they were only fit to minister to the ordinary exigencies of surgery? What had made them better surgeons than themselves? Was it cutting into the bladder and finding no stone? Was it leaving stones between the ends of the bone in compound fracture? He, Mr. Davis, had had seen a document which had given him much delight. The medical staff acting in the recent war in India had been thanked for their services: were these gentlemen to come home and be told they were no surgeons at all? Did Mr. Keate mean to tell him (Mr. Davis) that he was no surgeon? Did Mr. Keate mean to say that his own uncle was a fool or a rogue? Mr. Keate's uncle had told him (Mr. Davis) that he was a surgeon fit to serve in any of her Majesty's regiments. Did Mr. Lawrence mean to say that Mr. Abernethy was unable to decide on his (Mr. Davis's) competency to act as a surgeon? Mr. Davis was of opinion that to attempt conciliation with the College of Surgeons would be the extremity of folly.

Mr. Bowling, of Hammermith, said that, if he understood the meaning of forbearance, it applied not only to public bodies, but to individuals. There was something in the report which he objected to—it was a personal matter. He thought all individuals should be taken into consideration. The committee should have every support, and he hoped no private animosity would interfere to prevent it.

The resolution, as modified by the committee, was then put from the chair, and crried as follows:—"That the committee of the National Association be requested to continue their functions as a provisional committee, and with power to add to their numbers, for the purpose of carrying out the two last resolutions, and that a future public meeting be called, as soon as the committee may be prepared, to receive a report from the committee of their proceedings, and of the opinions of the profession on the formation of a National Institute of Medicine, Surgery, and Midwifery."

Mr. Fuller rose, and said that, if any one resolution more than another required unanimity, it was the one he was about to read.

Resolved:—"That this meeting is fully sensible of its deep obligations to the Society of Apothecaries for the enlightened policy with which the society has striven to create and maintain a high standard of qualification for the general practitioners; that this meeting highly applauds the conduct of the society during the recent discussions on medical affairs, also for their recently expressed determination to put in force the provisions of the Act of 1815, against unqualified practitioners, and it desires to convey to them the best thanks of this meeting for their able and disinterested advocacy of the claims of the general practitioners of this country."

Many of the gentlemen present could, he (Mr. Fuller) had no doubt, remember the state of the profession previously to the passing of the Apothecaries' Act; it could not be expected, however, that every one should know its benefits, but every one well knew what was due to the Society for the exertions they had made to raise the standard of medical education. They (the Association) should take example by that Society, and pursue their object with the same disinterestedness and the same devotion that the Society of Apothecaries had pursued their elevation. Labour and perseverance must lead them to the goal.

Mr. Martin, of Reigate, had great satisfaction in seconding the resolution. He was an old practitioner, and could remember the state of the profession before the passing of the Apothecaries' Act in 1815, and he could bear testimony to the advantages the profession had derived from it.

The resolution was put from the chair, and carried with considerable applause.

Mr. Nussey with pleasure asked the meeting to adopt the resolution he held in his hand; it was a resolution in favour of the honorary secretaries of the Association, Messrs. Bird and Ancell. (Great applause.) He would read the resolution. "That this meeting desire to record their unfeigned and grateful thanks to their honorary secretaries, Messrs. Bird and Ancell, for the devoted zeal and ability with which they have discharged the important duties devolving upon them; and although, in the opinion of this meeting, it would be impossible to express in adequate terms the obligations conferred upon the profession at large by their disinterested and efficient exertions, yet they are anxious to express their unabated confidence and cordial approbation as well as their high appreciation of the services rendered by those gentlemen."

(Whilst reading the resolution Mr Nussey was several times interrupted by unmixed marks of approbation.) No public body had ever before been blessed with such zealous functionaries as the honorary secretaries of the National Association. In the two all the requisites were combined. Thanks were but a poor return for services such as theirs, and he hoped that whatever the fate of the institution they were about to form, the profession would confer some more substantial mark of their gratitude on those who had given their time and talents so devotedly to its service. (Great applause.)

Mr. Bowling could not speak too highly of the zeal and merit of the honorary secretaries. The report read that night was sufficient proof of their talent. He seconded the resolution.

Mr. Bonney said that a great change was about to take place, and many of the gentlemen sitting in the audience part of that meeting would by and bye be sitting in the council. These gentlemen would then have an opportunity of appreciating the talent and zeal with which the honorary secretaries smoothed all the difficulties in their path. The meeting would allow, that although the most ungenerous attacks had been made on the committee generally, and especially on the honorary secretaries, they on the other hand, had been ambidextrous, and had repelled those attacks. With such zealous officers he hoped they would convert the opposition which had been shown them into a means of support.

The resolution was put and carried with great applause.

Mr. Clifton hailed with pleasure the unanimity which had prevailed that evening as a good omen of future success. He trusted all would join heart and hand, and use every exertion to carry out the objects of the Association. He had to beg their attention for a few moments to a resolution he was sure they would receive with pleasure. He would read it—"That the thanks of this meeting are due, and are hereby given, to our highly respected president, for his zealous attention to the interests of his professional brethren, during his presidency of the National Association, and also for his able conduct in the chair on this occasion."

He need only refer to the manner in which the chair had been filled that night to show the claims of the president to the thanks of the Association.

This resolution was carried by acclamation with great applause.

TO CORRESPONDENTS.

Mr. W. H. P. *imposes on us a difficult task. Mr. J. Churchill has been active as a publisher, but must be so engaged now in winding up the affairs and ending the litigations of the numerous unsuccessful railway companies of which he was a provisional director, that he may possibly not have the leisure necessary for so peculiar and responsible a work as that designed by our correspondent. But we forbear an opinion. The other medical publishers are Mr. Renshaw, in the Strand; Mr. Baillière, of Regent-street (who has the advantage of a large continental connection); Mr. Highley, of Fleet-street, who is still in business; the Longmans, of Paternoster-row; Simpkin and Marshall; Sherwood and Gilbert, &c. Mr. VanVoorst is the principal publisher of books on geology, physiology, and comparative anatomy. Our correspondent is further informed that it is against our rule to address private notes answering questions of the kind above proposed to us.*

Blue Jacket.—*One of the articles will be found in Dr. Williams' Course of Lectures on Medicine; the other, probably, in some notice of a surgical book on the subject. Our correspondent is referred to the* Indices *of the* Medical Times.

A Retired Surgeon *mentions a very important fact about which we should be glad of further information. Sir Robert Peel's measure will undoubtedly place the medical officers of unions in a better position—how much so we are unable* yet *to say.*

Justitia.—*The operation is the* setting *whence the hours specified commence to run. We doubt the legal validity of the claim.*

M. D. (a Subscriber) *must excuse our non-publication of his letter. A meeting of thirty persons, of whom, at least, ten attended, like our correspondent, to observe and report progress, requires no such prolonged notice. The only strange feature was the presence of one gentleman who appears to hold his person and position a* little *too cheap. As of the toad inclosed in stone we may say with Pope—*

> The thing we know is neither rich nor rare
> But wonder how the d——l it got there.

A Reader.—*The manual of Guy.*

X. Y. *is declined, as also several other correspondents.*

Many papers have been received which we cannot use.

THE MEDICAL TIMES.

SATURDAY, APRIL 25, 1846.

"Forti et fidele nihil difficile."

NEVER was it better evinced than on Friday last that a cause may gain as much by factious and unprincipled opposition on one side, as by moderate, firm, and prudent support on the other. The great meeting of the National Association was one continuous triumph to the Committee and Honorary Secretaries. The objects for months of declamatory vituperation in shadowy Associations without members, and death-stricken journals without readers, the members of that Committee called a public meeting of the Profession to decide between them and their accusers. The assailant was present—the man who had maintained for years—thank heaven, it is no longer maintained!—a reign of moral proscription over the Profession. The accused Committee took the highest ground; they claimed not pardon, nor indemnity, but gratitude and support; they indignantly repelled accusation; met insinuation and invective with a virtuous and haughtily-expressed contempt: their vindication was the brief, proud, and contumelious retort of firm-seated virtue bearding noisy unprincipledness. The result? The meeting "applauded them to the echo" that did "applaud again." And the assailant? Abashed and cowered, he hung down his recreant head, his accusations abandoned, not one word dared—not even in his own exculpation. It was, indeed, a shocking sight, and adds one striking leaf more to the annals of retributive justice. Sooner or later—it again comes out—the public—supposed so blind—will not fail to mete out to each his deserts. The fact deserves emphatic chronicling. Though personal, it has the utility of a general application.

While the Committee's vindication of their past conduct is thus offered as a triumph, their programme of future operations will be accepted as not less satisfactory. The chief interest, of course, centres in the proposal of a new Institute of Medicine.

Our readers will remember that we have long pointed to this as the inevitable result to which the madness of the Council of the College of Surgeons must lead us. We foresaw, from the moment they stopped short in the improvements they designed, and we were authorised to announce for them, that their doom was sealed as a national institution, and that the Profession would ultimately be roused—nay, compelled—to take a decided course of their own, and that the steps which then looked extravagant, as improbable, would, in the course of a very short time, be adopted universally as the suggestions of a most judicious policy. The consummation so much desired by us—so little expected by many—is now before the public. It is forced on our acceptance. We have no choice but to adopt the boon. The National Association *could* do nothing worthy of itself but propose the New Institute of Medicine and Surgery; and the Profession can do nothing not dishonourable, pusillanimous, and unwise, save by accepting it. The new measure is the new necessity of our position.

The Committee have done most wisely in bringing forth the project in the *deliberative* fashion announced in their report. It is a vast design, and if the new institution is to have any permanence there must be no hasty, frostwork architecture. It is a thing not to be accomplished by the quick legerdemain and active trickery which have been so currently mistaken for wisdom by the managers of other Associations. All must be done thoughtfully, carefully, honestly, fearlessly. The building must be begun from its foundation, and before beginning, we must be sure that we have not only the plan, the architect, and the workmen, but also a complete supply of the materials. We must have no commencing and leaving off half-way. We must not begin without being sure of ending. What makes this prudent course the more eligible in this instance, is the fact that success can only be precluded from us by our own fault. All its elements are in our own hands—and just as one premature step might ruin all, a succession of prudent ones must secure all. It is to be recollected, too, that the duties which are to win the ultimate triumph do not rest wholly on the Committee. These gentlemen are of no force save as the instruments of a large and active body of professional brethren. Like ambassadors at a foreign court, they are strong, not in their own strength—influential individually, as they may be—but in the strength of those they represent. Well supported, they may fail; but ill-supported, they are certain of defeat.

Wisely, therefore, after enunciating the *important proposition that the Profession should organise its own college*, do they decline to take one compromising step towards its establishment, till they ascertain in what degree and to what extent they can count on effective co-operation. In their own words—

"They apprehend the proper course would be to employ the machinery of the National Association for the purpose of canvassing the members and the profession generally, by circular letter, to ascertain whether they are desirous of entering into such an undertaking. If they are not disposed to do so with zeal, and even with enthusiasm, or by some other means to maintain an effective organisation, all amelioration of the condition of general practitioners is hopeless. It would be unreasonable to expect that a few individuals could give the time and attention required, and subject themselves, even in a great public cause, to the anxieties and responsibilities which must necessarily be engendered, unless they receive the encouragement and assistance of a very numerous body of the profession."

In the very proportion in which this "encouragement and assistance" are necessary are we hopeful of their extension. It is quite right that the Profession should not have the fact blinked to it—as is customary with some associations—that its energetic aid is a *sine quâ non*. Medical men have never been known to shirk a labour because it appealed to them in the shape of a responsibility. Bring home to them a sacrifice of time or money as a personal duty and social obligation, and you are sure that it will be made, and when the Committee tell their brethren frankly, unless it be your will to approve and aid our design, we shall not feel justified in undertaking the labour, they make an appeal for co-operation, sure—or we mistake—of a hearty and general response.

The strictures of the Report on the unfortunate Surgical Council were as justly severe as they were abundantly called for. The meeting was loud in its cheers of the few caustic sentences. In the council chamber the feeling expressed on this evening should awaken lively sentiments of shame and uneasiness. As it is, some of the better-mannered Councillors are said, even in social life, to shrink from facing their injured fellow members. They feel a becoming difficulty in looking into the eyes of those whose trust they have betrayed, and whose credit they have infringed.

The liberal standard the Committee adopt for regulating the question of membership of the "Institute," seems to us most judicious. In medical politics we must give and take; and if we aspire to legislate on exclusive principles, we *aim* not to comprehend in our scheme more than a section. The basis of the medical structure cannot be too broad, consistently with our existence as a profession. After ensuring the incorporation in one establishment of every legitimate practitioner, we may then enter on a discussion of grades, and classes, and distinctions. Before that be done, it is only so much waste of argument and useless dissension.

The preservation of the Association, independently of the project of the institution, is not only proper but essential. The Committee of the Association must launch the new vessel, and, till its seaworthy qualities be tested, it would be most unwise to abandon the craft that has more than once so gallantly weathered the storm for us. There is no wisdom in being off with the old love before we are on with the new.

Malorum immensa vorago et gurges.—CICERO.

Qui dit docteur, ne dit pas toujours un homme docte, mais un homme qui devroit être docte.—ST. REAL.

TOWARDS the close of the sixteenth century, lived an enthusiastic fellow, in Ancona, named Horace Augenio, who adventured a couple of experiments in physic, that took amazingly with the people. Knowing, as all sagacious men do know, that if you are to get rich by a novelty, it must be by one that is very unmistakeable in its pretensions, he dashed randomly at a remedy, as dirty as it was deceptive, and got his pockets well filled for his artifice. He wrote a book of medical epistles and consultations, in which he vaunted the curative virtues of millepedes in vesical calculus. The strangeness of the remedy, and the strong faith he affected to place in it, would no doubt have won the confidence of the multitude, but he preferred catching hold of their credulity with an instrument not likely to lose a victim, having once fairly hooked him. This instrument was a TESTIMONIAL. Its donor gravely declared, that, for a certain length of time, he was the subject of stone in the bladder; that he consulted physicians of eminence who vainly endeavoured to relieve him; and that he was at last condemned to an operation as the only

chance of having his life saved. Hearing, however, of the fame of Augenio, he submitted himself to the skill of this wonderful man; and, after having been well dosed for some time, with his marvellous millepedes, all symptoms of stone vanished, and he was once again as hale and hearty as he had ever been. Personal avowals, that are founded upon personal experience, are very difficult to contradict and hence, if they are given boldly, and with a liberal sort of colouring, they rarely fail of making plenty of believers. So it was in the case before us: the man said he had been cured of calculus—and of course he ought to know—and the public placed implicit belief in his statement, without ever pausing to weigh the possibility of his having been paid for giving utterance to a falsehood. One might almost be induced to consider such public as somewhat unique in foolishness, did not our own more enlightened age furnish examples of folly, much more conspicuous and contemptible than theirs. Experience has done nothing towards lessening the tendency to this voluntary delusion—hecatombs of victims have testified to the danger of credulity in physic, and yet their crazy followers are not deterred from plunging themselves into the same vortex of ruin. An impostor has only to announce that he can cure consumption, or cancer, or any other ailment that his fancy may hit upon and forge a few notes purporting to come from individuals upon whom his miracles have worked, and, forthwith, he has followers in good plenty who are ready to pander to his impertinence and villany with their last shilling! Only let him have capital enough to command a nook in some newspaper of fair circulation, and the money he expends in advertisements will be returned to him a hundred fold!

I revert to our hero—the value of his remedy was established at once—it cured everything that came before it—and, at last, died a natural death, at a good old age, after having rewarded its discoverer with a more than moderate fortune. It will be remembered, that, a few years back, this piece of empiricism was attempted to be brought into fashion under the pretext of its novelty. It was only a revival of an old system of robbery which had slumbered for more than two centuries, and was again introduced to the living world to enact its roguery afresh. It answered not unprofitably, but less fully than of yore; and was at last condemned to a second death, but only to give place to other imposition in the same line, as worthless, and even better rewarded.

Augenio's other secret remedy was for worms. He performed many extraordinary cures with it, and was, consequently, a large gainer, both in reputation and pocket. It was at last found to consist of water, which had been boiled in contact with mercury, whose oxide, if any were present, might impart some little activity to the water. Strangely enough, directly that the nostrum was known, its charm was dissipated, and it failed to be as curative as aforetime. By degrees it fell into disfavour, and at last left the market altogether. Some few years back this same remedy was revived by a lady, who ushered it into the world as something new. Scammony, jalap, calomel, turpentine, and other such things, were inert compared with it—desperate cases, that defied *them*, yielded readily to *it*, and a tœnia or a lumbricus had no more chance with it, than a trout, well-hooked, would have had with Isaac Walton. Gradually it lost its power, then its popularity, and finally, the people found wisdom enough to inform themselves that it had most egregiously deceived them. We should not wonder, however, to see it some day revived again, with plenty of fresh credulity to feed upon.

Guy Patin, who reached the height of his popularity about the middle of the seventeenth century was a man of great ability, erudition, and medical knowledge. This fact was well known, but it stood him in no service, for of the thousands who applauded, not one employed him. At last, the crotchet seized him to write an abuse of antimony. Under the title of "Antimonial Martyrology," he published a book, in which he levelled a volley of invective against the drug, and backed up his prejudices with a record of numerous cases in which it proved hurtful. There can be little doubt that he was as incompetent as he well could be to the task he took upon himself, but it gave him what the world considered a *practical position*, and forthwith he was ranked amongst the fortunate number of *practical men*. Never was a deception worthier of being laughed at. Patin wrote nearly forty works in French, Italian, and Latin; and yet, it would have puzzled him to have diagnosticated a case of small-pox, or to have distinguished, precisely, a common cold from a consumption. "There is a tide in the affairs of men"—there was one in the life of Guy Patin—he took "the current when it served"—and the "venture" was not lost to him! Such has been the unworthy fate of many a man since his time. Often has a thickhead, in a prodigality of invective, raised himself into repute by a wholesale denunciation of some particular drug. Salmon "put money in his purse" by telling the people that fox-glove would cure consumption; but many more have been yet better rewarded for saying that fox-glove would do no such thing. It would be interesting to know how many fortunes have been made by praising and persecuting mercury! It has been a target for medical sharpers to shoot at ever since Paracelsus took it under his patronage.

An old rule, in a favourite game of cards, tells you, when in doubt, to "play a trump." This suggested a trick that Curran had, of quoting Latin when he fell short of English. So it is in physic—do something to distinguish yourself, no matter what—get your name up, and you will get your fortune! We blush when we say that the phrase has some truth in it. Make a book—if you can, by writing something up; if not, by writing something *down*. *Sic itur ad astra.*

Sylvius was not a quack at heart, but he was one day seized with a fit of prejudice in favour of the doctrines of Van Helmont, and forthwith he began to prescribe only according to the suggestions of chemistry. A certain personage was so profoundly skilled in a certain science,

> "That he could tell what time o' day
> The clock would strike, by algebra."

So it was with Sylvius. He conceived sundry notions about acids, and alkalies, in the system; and according as one predominated, he prescribed the other. He made such a fair show of reasoning upon the matter, that many were converted to his faith; and not a little was rational pathology retarded by the absurd fancy that the living machine was nothing better than a laboratory. The dogma had its day, and then fell into discredit. We are not without our fears, however, that something like his old folly is being revived amongst us. The daring theories of Liebig have attracted many disciples to them, and those of the junior school, who are wanting in bedside experience, now affect to make up for legitimate pathology, by bits of coloured paper, and a few little bottles and test-tubes. There is nothing too dirty for this race to do. We remember the time when a practitioner was satisfied with seeing fæces, and smelling them; but this does not half satisfy the modern school of chemical pathologists. They will poke test-paper into a night-chair, and rejoice in dirtying their fingers; and gladly carry home a fragment of the filth, to see how much fat may be in it! All this, they solemnly declare, is essential to a correct knowledge of the disease; and mightily gratified, of course, is the patient, in the thought that even the unworthiest part of him commands such serious attention! Urine, again, has lately become as valuable as if sticks of phosphorus were found ready-made in it; and, in the hands of some men, it is a talisman of such certain power, that it constitutes a regular "open, sesame," to any disease the body may be labouring with. This toying with chemistry we have curiously watched for some time past, and are only anxious to know how long it will be before the absurdities are all exploded, and the legitimate services of the science made properly and unpretendingly available in the business of the bedside. We are old patrons of it ourselves; but we have so often witnessed its abuse, that we have grieved over its misapplication. We desire to see it honourably enlisted in the cause of practice of physic; but we do earnestly hope that, in the hands of adventurers, it may not be made an ostentatious means of fostering and furthering quackery. We are suspicious that the evil of it, already set a-foot by the venturesome, is likely to spread, because of the temptation that it offers to the inexperienced to give it countenance; but we must trust to the more enlightened of the profession to chastise the folly, whenever they find it threatening either the honour of our calling, or the integrity of the principles upon whose careful cultivation we can alone rest with the hope of advancing the science of legitimate physic. Especially, however, do we urge, that the absurdities of the new chemical system—those absurdities which threaten our pathology—may be arrested while they are yet young. Chemistry, as applied to the practice of physic, is a most useful adjunct, both of diagnosis and therapeutics, in the hands of men sufficiently well skilled to be competent to form upon it a rational opinion. In the hands of inexperienced men—to whom we fear its serious truths are becoming too often committed—we do not hesitate to say that they are worse than worthless. Let this be corrected in time! *Malum nascens facile opprimetur; inveteratum fit robustius.*

TRANSACTIONS OF LEARNED SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Meeting of April 14, 1846.

Dr. Chambers, F.R.S., K.C.H., President, in the Chair.

Some Remarks on Wounded Arteries, Secondary Hemorrhage, and False Aneurisms; by Robert Liston, F.R.S., Vice-President of the Society, &c.

The author states that the subject of wounds of arteries, with the consequences of such wounds, immediate and remote, has possessed, and always must possess, great interest in the eyes of the surgical practitioner. His impression, until very lately, was that no subject had been better handled or was better understood by surgeons generally, and that all writers were pretty well agreed as to the rules which ought to guide the practice in such cases. When, however, we hear of an operation being performed upon a large vessel on account of a recent false aneurism, after careful consideration of all the circumstances of the case by six surgeons, and when there is reason to believe that, at least, an equal number of respectable practitioners (not, however, engaged in the case) were ready to declare the practice pursued very wrong, and contrary to the established principles of surgery, and thus, had

the vessel not been tied, the patient might now have been alive, it is surely desirable that an opportunity should be afforded of discussing this subject, and, if possible, settling the question in dispute. The author then proceeded to relate very shortly the leading facts of the case, and to support the line of practice pursued by reference to, and relation of, some similar instances.

Mr. S., aged twenty-eight, an exceedingly corpulent person, who had, it appears, lived excessively freely for a series of years, was wounded on the 20th of May, 1845, by a pistol-bullet. It entered the upper and outer part of the right thigh, and passed out in the middle of the fold of the left groin; thus traversing the course of the femoral vessels. The flow of blood, more especially from the wound on the right side, was described to have been most impetuous and profuse. It was thrown in jets to a considerable distance. The patient was found by Mr. Jenkins, of Gosport, in an almost lifeless state, and he was with great difficulty recovered from the syncope and depression. A considerable swelling soon supervened over the lower part of the abdominal parietes from extravasation of blood.

May 27th, the seventh day from the receipt of the injury, the swelling in the right groin began to increase in size, and distinct pulsation was then, for the first time, perceived in it. The tumour went on increasing gradually, and it had gained much more in bulk on the tenth day, when Mr. L. first saw him, than it had done on any of the preceding ones. It was of an oval form, and elastic, but firm, as if it was partly made up of coagulum and liquid blood; but it could not be at all diminished in bulk by uniform and continued pressure. Pulsation was strong and distinct in all its parts. The opening on the right hip was filled with a dry depressed slough; the wound in the left groin, a jagged slit, was closed by a very thin cicatrix. The patient's countenance was blanched and waxy, and his pulse quick and feeble. He had, in short, all the appearance of a person who had lost a great quantity of blood.

The nature of the case was very apparent A large false aneurism, not well bounded, rapidly increasing, and arising from a wound of the femoral artery, or some branch divided close to its origin, had to be arrested, otherwise the patient must be left exposed to the risk of perishing suddenly, and at no distant period. After consultations, on the evening of the 30th and morning of the 31st, the external iliac artery was tied, with the loss of not more than a tablespoonful of blood, and with the immediate effect of arresting the pulsation, and removing, in a great measure, the tension of the tumour. Symptoms of peritonitis supervened the same evening, and on the following afternoon the patient sunk.

The author subjoined an account of the post-mortem examination by Dr. Allen, of Haslar. The course of the bullet was traced from the outside through a dense layer of fat, about two inches in thickness. It had divided one of the superficial branches of the femoral artery, about half an inch below Poupart's ligament, and about an inch from the main body of the femoral artery, which had caused a false aneurism. The sac contained about three ounces of blood. No other artery appeared to have been wounded. A considerable quantity of sero purulent fluid was found in the abdominal cavity, and patches of acute inflammation were observed on the intestines. The peritoneum adjoining the wound of the operation was inflamed. It had not been injured by the knife. The ligature had been properly applied to the external iliac artery. The abdominal viscera were healthy, but loaded to an extraordinary degree with fat. There was some enlargement of the right limb, but apparently no mortification. The femoral artery was pervious. The blood in the aneurismal sac was firmly coagulated, and there was no mark of recent oozing from the injured artery. The ball had passed immediately over and along the course of the artery for about half an inch before dividing it. The artery, although not actually detached, would not have borne a ligature.

That a vessel of this class, the author remarked, should have bled so furiously, in the first instance, could not have been anticipated. Having done so, one can so far understand the active pulsation and rapid extension of the tumour. It was, of course, quite impossible to determine whence the blood flowed into the aneurismal cavity. The principal vessel going to the limb might have been wounded, or some considerable branch. A small branch, divided close to the principal vessel, poured out blood furiously, as much so as if an opening in the coats of the artery itself were made by a portion being punched out, corresponding in size to the area of the branch. The division of a small branch at a distance from the source from which it springs is of little importance. It contracts, and soon ceases to bleed; but when it is divided close to the trunk, blood issues from it, as it would if an opening, equal in size to the calibre of the little branch, were made in the trunk itself.

The author noticed the risk of secondary hemorrhage in these cases, in order to show that some active measures were required to arrest the threatened danger. He objected to the operation of opening the sac, and securing the wounded vessel by ligature; that patients who have lost a great quantity of blood are often sunken and lost by the sudden effusion of even a small quantity, and, after adducing some cases in point, he remarked that the danger must be much enhanced when the tumour is so placed that there is no possibility whatever of making pressure on the trunk of the artery on the proximal side of the opening into it, or of the origin of a branch wounded close to where it is given off, as in the case of Mr. S. The cyst could not have been opened without great loss of blood, and it was not likely that a ligature on the branch would have permanently arrested the bleeding; indeed, it was stated by Dr. Allen that the trunk would not have held a ligature.

The author having asked whether there is anything to bear a surgeon out in adopting this practice, adduced a number of cases to show that vessels bleeding outwardly, or pouring their contents into the tissues of a limb or region, have become permanently closed in consequence of the flow of blood being intercepted and weakened for a time by the application of a ligature upon the principal arterial trunk. He referred particularly to a case to be found in the works of a well-known army-surgeon. A man, thirty years of age, was wounded by a musket-ball, which entered the left groin, and passed through the inside of the thigh. On "the tenth day from the injury, the slough from the anterior wound came away, and was followed by so frightful a hemorrhage as to leave no doubt whence it proceeded, nor, from the wound being so high up, any alternative as to the means to be adopted for stopping it" The external iliac was tied, but the patient died of fever. No account is given of any dissection of the parts. "In this case the necessity of the operation is evident, and, as far it went, also its success. Not a drop of blood was lost after it." So says Mr. Guthrie, who, it is to be presumed, conducted the treatment of the patient. We are left to conjecture what vessel was wounded. It may have been a branch, as likely as the trunk, and those who have attended to the description of the hemorrhage in the case of Mr. S., to its impetuosity and amount—will bear the author out in this assertion.

The author observed that he has endeavoured to show: 1st, that the case of Mr. S. was one of great and immediate danger; 2nd, that some decisive step was required to be taken, and that without a day's delay; 3rd, that very great risk would have been incurred in attempting to put a ligature on the wounded vessel; 4th, that there was ample authority for adopting the step which was had recourse to in this case. The dangers likely to arise from the operation were considered as weighing but lightly in the scale against those impending from the effects of the pistol-shot. Inflammation of the peritoneum was scarcely taken into account in consulting on this case Out of the forty-five cases of this operation, collected by Mr. Crisp, nine or one-fifth died, but not one from peritoneal inflammation.

In conclusion, the author remarked that, in the opinion of those concerned, the step most likely to avert danger, and prolong the patient's life, was adopted—the only step, it has been shown, that could have possibly been resorted to with propriety or safety. Upon a candid review of the case, and with a knowledge of all the circumstances connected with it, it now remained for the fellows of the Society to say if there was left anything undone, or anything done imprudently or unscientifically, as has, it appears, been alleged. It is competent also to consider what might have been alleged against the resources of our art had the patient suddenly perished from hemorrhage; if, in fact, we, who had all the responsibilities of this important case to sustain, had stood idly by, waiting for some miracle of nature to save the patient from the inevitable results of his wound, and the author of it from the consequences of his crime.

Mr. Edwin Lee remarked, that several of the cases which Mr. Liston had adduced did not seem to him to bear upon the point under consideration, viz., the advantage or disadvantage of tying the external iliac in cases of wounds of that vessel, and more especially of either of its branches, inasmuch as in ligature of the femoral, brachial, ulnar, tibial, &c, there are abundant means in the collateral and anastomosing branches for the supply of the distal portion of the extremity with blood; whereas the iliac is under peculiar circumstances where tied, giving off no branches above the ligature, and those from the internal iliac (gluteal and ischiatic) being distributed to the muscles of the hip and back of the thigh, there would not be sufficient means, after the ligature of the trunk (considering that the whole of the lower extremity is implicated) for the supply of the limb with blood, and that, consequently (setting aside the dangers of peritoneal inflammation, &c., as immediate consequences of the operation), mortification must ensue—as it appears it did in the two or three cases cited by Mr. Liston, where the iliac had been tied for wounds or sloughing in the groin. The case is widely different when this vessel is tied on account of long-standing disease—aneurism—from that of a wound when the person was a few days before in robust health, as the tumour must gradually obstruct the circulation through the principal trunk, thus affording abundant time for the dilatation of other vessels sufficiently after the application of the ligature, &c., to supply a limb which has long been in a quiescent state with blood, and he believed it would be found, that these are the only cases in which recovery has taken place after this operation.

Mr. Bainbridge observed, that the case, as detailed by Mr. Liston, furnished in itself a complete condemnation of the treatment. It proved the diagnosis to have been incorrect, and the treatment equally so; he (Mr. Liston) had acted in the belief that a large and important artery was the seat of the injury, and performed a painful and dangerous operation for the cure of an aneurism formed by a trumpery little artery, which might have been readily cured by the application of compression. He (Mr. Bainbridge) then narrated a case which he considered to bear directly on the treatment of such an aneurism by the use of pressure. It occurred last August to a man who was accidentally wounded in the wrist by a clasp-knife, by which the tendons and radial artery were divided. Considerable hemorrhage ensued, which Mr. Bainbridge arrested at the time by the application of the tourniquet over the brachial artery, while he got ligatures ready. On loosening the tourniquet afterwards, preparatory to applying a ligature to the wounded vessel, he found that the hemorrhage had ceased, and consequently judged that the artery had retracted, and that there was not any further need of ligaturing it. He therefore closed the wound with adhesive plaster, and applied a compress and bandage. Hemorrhage recurred in a few hours, but was arrested by pressure on the artery above the wound. It soon recurred, and was again stopped; it then ceased for a week, bursting out afresh when the wound was dressed. A fortnight afterwards there was found a false aneurism of the size of a large walnut, situated at the root of the thumb, and extending between the metacarpal bones of the thumb and forefinger. The aneurism was accompanied by considerable œdema of the thumb, hand, and fore-arm. Mr. Bainbridge applied a cork, padded with lint, over the aneurism, and secured it in situ with plaster and bandages; and he also applied compression to the artery above the seat of disease. A bandage was also placed loosely round the limb, so to enable the patient by drawing it tight to command the hemorrhage, should

it recur, which it did a few days afterwards from the aneurism itself. Several days after the recurrence of the last hemorrhage, the aneurism on examination was found to be much increased in size. Compression was then applied by means of a graduated cone, made of pieces of cork wrapped up in lint, the apex of which pressed directly upon the aneurism, and together with this the other precautions were used the same as before, to wit, pressure on the artery above, and the application of an additional bandage loosely round the arm, intended to command hemorrhage if required. This apparatus was kept applied for a fortnight, portions only being loosened when complained of, and after the lapse of that time, when the part was examined, there was a deep indentation in lieu of the aneurism, and all pulsation had ceased. The bandage, &c., were continued for some time longer, after which the man was enabled to return to his occupation. Mr. Bainbridge inferred, from the success he had met with in the treatment of this case by compression, that a similar plan would have been effectual in the case which Mr. Liston had brought forward, and he blamed Mr. Liston for not having had recourse to it. The requisite pressure he thought might have been obtained from a common spring truss, applied on the groin, by which the small artery, whence the hemorrhage proceeded, would have been compressed as it passed upwards over Poupart's ligament, and the femoral artery also, as it lay upon the pubis. Mr. Bainbridge then, in allusion to the exceeding severity of injuries from which recoveries are sometimes made, referred to the preparations in the Hunterian Museum, illustrative of Sir Wm. Blizard's case, in which the shaft of a gig was driven through a man's chest, and yet recovery took place, and the man survived the injury many years. He thought the comparison between such an injury and that inflicted on Mr. S. was very slight, and he (Mr. Bainbridge) concluded by saying that, in his opinion, Mr. Liston had not shown the caution and correct judgment which might have been anticipated, considering the high position he held in the profession.

Mr. Liston remarked that he was not in any way cast down by the observations which Mr. Bainbridge had made. The case of Mr. S. had been the subject of very severe animadversion, but he had acted at the time under very good advice, and, after due consideration, had brought the full details of the case before the Society. It was quite impossible to say beforehand what vessel had been divided. It bled very freely at the time the injury was received, and afterwards the hemorrhage continued internally, a large tumour, pulsating violently, being formed, which was likely to burst at every moment. The danger threatening the patient was not imaginary. In bringing the case before the Society, he wished to state that he had written to several gentlemen, who, he understood, had criticised his practice in this case very freely, but for some reason or other they had declined attending that meeting. He then read an extract from the *Glasgow Medical Journal*, alluding to the details of a case of secondary hemorrhage from sloughing of the groin, in which Dr. Buchanan had successfully ligatured the external iliac artery, and to which the following remarks were appended by that surgeon :—"It may be said of these operations that more of them were required by the strict rules of surgery, which enjoins, in cases of arterial hemorrhage, that we should cut down to the place from which the blood is observed to issue, and there secure proximal and distal portions of the injured tube. All most true, and I most gladly subscribe to this aphorism, along with your regular system compilers of surgical treatises, manuals, and compendiums; but, alas! in actual practice, how many exceptions are we compelled to make! What would such mechanical men of principles have said had death taken place (as undoubtedly it would) in attempting to secure a sloughing, soft, and diseased arterial tube? Why, that I ought to have first tried what a ligature thrown round the iliac artery could accomplish, and if a clot did not form, *as in all probability it would*, then recourse might be had to the *dernier ressort*—the ligature of the distal side of the hemorrhagic spot; also, true it is, however, you must lay your account when you advance in practice to meet with animadversion, and *criticism, do which you will.*" He (Mr. Liston) could not understand the gist of Mr. Lee's remarks. They did not appear to him to have any direct bearing on the case. As to the case narrated by Mr. Bainbridge, it seemed to him to have been mismanaged from beginning to end.

Mr. Bainbridge thought that Mr. Liston had committed an error in judgment in not knowing what artery had been wounded, and he added that, as his patient recovered, and Mr. Liston's died, there was presumptive evidence that he had managed the better of the two.

Mr. Edwin Lee explained that his objection to the performance of the operation which Mr. Liston had adopted, was based on the fact that the collateral circulation would not be sufficient to maintain the life of the limb, and that consequently there would be great danger the occurrence of mortification.

Mr. Liston agreed with Mr. Lee, that when the external iliac artery was tied under such circumstances, there would be the probability that mortification of the lower extremity might take place; but he thought the surgeon was not to be prevented by the anticipation of such a result, from applying a ligature to that vessel if it were required. He had seen over and over again that such a result did not always attend the application of a ligature to the external iliac artery. There is, however, the risk of that consequence, and the lower part of the limb had been more than once amputated in consequence. He wished to add that if a case similar in all respects to that of the late Mr. S., were to occur again in his practice, he should feel himself fully justified in adopting the same operative proceeding.

Mr. Hilton observed that as the legal inquiry into the circumstances of this case had not been concluded by the trial of the principal, and as that person's life was at stake, he thought it would be better that the discussion on which they were entering should be postponed. He made this proposition without any intention of offering offence to Mr. Liston.

Mr. Arnott, in seconding this proposal, observed that, although he considered the principle a sound one, that a wounded artery should be secured at the seat of injury, yet in this instance he believed that Mr. Liston had fully made out his case. Mr. Liston was not called in until ten days after the patient was shot in the groin, by which time an aneurism had formed, and there was not any situation above the wound at which the artery could be compressed. Mr. Liston had not opened the entire question abstractedly, but had confined himself to the details of this special case, in which there had been a large quantity of blood lost, and the patient was pallid and exhausted, and he (Mr. Arnott) thought that Mr. Liston had adopted the only operation which was admissible under the circumstances.

Mr. Dalrymple, in respect to the observations made by Mr. Hilton, stated that the surgical part of the question had been fully decided by the learned judge at the late trial, and that, consequently, the character of the discussion that evening could not have any bearing on any future trial. He thought that the remarks which fell from the judge on the occasion to which he alluded, afforded a sufficient justification to a man labouring under great prejudice and misrepresentation, for bringing the case forward at that society. He (Mr. Dalrymple) thought that the case narrated by Mr. Bainbridge had not any bearing on that described by Mr. Liston. The injury which Mr. Bainbridge's patient suffered was one that was well known, and he could not understand why Mr. Bainbridge had not applied a ligature at once to the artery, when he was aware that it had been divided, and had retracted; and must have anticipated the occurrence of secondary hemorrhage. There was no analogy, he thought, between the application of a pad in this case, and the treatment of a large aneurism in the groin which was on the point of bursting.

Mr. R. Quain remarked that if the discussion then pending could have any influence on the future trial, it had better be stopped at once. Mr. Liston, however, had admitted that his patient died from the immediate effects of the operation, and that was the utmost any counsel could urge.[1] He thought, therefore, that Mr. Hilton's fears were groundless. With respect to this case, the first question that arose, was as to the necessity for any operation, and in considering that question, he would bear in mind that Dr. Mortimer and other gentlemen, of whose assistance Mr. Liston had availed himself, were men of great experience, and he consequently was fully of opinion that an operation was requisite. Then came the next question, was the operation that was performed the right one? He agreed with Mr. Arnott that it was the proper operation, and he alluded to Dr. Warren's case recently read before the Society, in which the axillary artery had been wounded, and the subclavian successfully tied to arrest secondary hemorrhage. Mr. Bainbridge had alluded to the small size of the artery that had been wounded; this, he (Mr. Quain) thought could not be determined beforehand. Mr. Liston, however, had gone beyond this; he had shown that a small vessel, when divided close to a large artery, may give rise to very dangerous hemorrhage, and in confirmation of this statement, he (Mr. R. Quain) mentioned that Mr. Stanley, in operating for hernia, at St. Bartholomew's Hospital, divided a small branch of the epigastric artery, and the patient died from the resulting hemorrhage.

Mr. Curling had very carefully read the particulars of the case as detailed by Mr. Liston, and he could not see any grounds for doubting the correctness of Mr. Liston's proceedings. He could not see the force of Mr. Quain's statement respecting the danger of severe hemorrhage. When a small vessel was wounded near a main trunk, he (Mr. Curling) thought there was sufficient contractile property in the coats of the vessel to diminish the aperture thus produced. Mr. Liston's case presented an anomaly in the very distinct pulsation which existed in the aneurism, and which did not admit of a clear explanation, on account of the small size of the wounded artery.[2]

Mr. Bainbridge stated that he should defer to the opinions of the gentlemen who had addressed the meeting, but he thought they had mistaken his position in the argument. He could not consider it any excuse for Mr. Liston, that the other surgeons in attendance on Mr. S. concurred in his proceedings, for if he had not recommended the operation, it would not have been done, and it is perfectly possible for six or seven physicians or surgeons to be in consultation on a case, and all take an erroneous view of its nature, and consequently advise a plan of treatment not suited to meet its exigencies.

SURGICAL SOCIETY OF DUBLIN.

[From our own Correspondent]

Meeting of the 4th of April.

R. Carmichael, Esq., in the chair.

A communication was read by the secretary, Dr. Benson, from Mr. V. W. Russell, of Limerick, on the efficacy of prussic acid in the treatment of convulsions in children.

The Secretary, and afterwards the President, in commenting upon Mr. Russell's cases, remarked that the details were insufficient to admit of an accurate judgment being formed respecting the value of the remedy, more particularly as a very small dose of the prussic acid had been given—the sixteenth of a drop; and as it had been administered in conjunction with calomel, it might be doubted whether the latter had not acted much the more important part.

On Diseases of Bursæ.

Professor Hargrave placed upon the table two casts, one of them representing a tumour of considerable size and long standing, which Dr. H. had removed from a man aged forty, admitted to the

[1] Mr. R. Quain's statement on this point is erroneous. The mere fact that the operation was the immediate cause of the death, could not in any way serve the prisoner. It must further be proved that the operation was unnecessary, or, if an operation were requisite, then that the one actually performed was not the right one.—*Rep.*

[2] The marked pulsation of the aneurism in this case was in all probability communicated by the femoral artery, which was in proximity with the aneurism.—*Rep.*

City of Dublin Hospital four weeks ago. The man had tumours on both knees, which had been gradually developed during a period of 12 or 14 years, his various occupations having obliged him to rest much on his knees. Though attended with occasional paroxysms of pain, he paid little attention to them, being anxious to work as long as possible for the support of his family; they both felt on examination excessively solid and firm, that of the right knee having on its surface a mammary pointed prominence, which had all the characters of a small circumscribed abscess, so much so, that Dr. Hargrave was strongly inclined at first to puncture it, and get rid of the supposed purulent contents previous to practising excision of the whole mass. The immense mass of foreign growth now exhibited lay in front of the patella, between it and its bursa, and was invested by a dense fibrous capsule, containing within it alternate layers of blood and fibrine, the mass being perfectly circumscribed—a point connected with its pathology which he considered very interesting. At the site of the original patellar bursa there was found a yellowish coloured fluid, not purulent, however, and immediately posterior to which, as already observed, lay the solid mass. The soft parts, at the seat of the operation, are now uniting by suppuration and granulation. The tumour of the left knee is partly ulcerated, discharging a thin sanguineous matter, while the remainder of the mass is in an exceedingly indurated condition. In other respects the man is perfectly healthy, but was unwilling to submit to the simultaneous removal of both tumours, though Dr. Hargrave was himself anxious to do so.

A discussion of great length, but of little practical interest, succeeded, in which the efficacy of the several operations of partial excision of the sac, puncture, subcutaneous section, &c., was warmly advocated by the different members present.

It was observed by Mr. Gordon, that at a late meeting of the Pathological Society, Mr. Adams had related some cases in which the removal of a portion of the sac had been attended with complete success; and that Mr. Adams preferred this mode of treatment to that of complete extirpation of the sac—a proceeding which he considers may often be attended with danger to the joint, besides that few would submit to the operation of extirpation. It was in a late number of Guy's Hospital Reports, Mr. Gordon believed, that the operation practised by Mr. Adams was proposed by Mr. Aston Key.

Professor Williams went considerably into the details of the subject, and remarked that the therapeutic indications as to treatment must at all times become subservient to the particular circumstances characteristic of the individual case. Among the many modes of treatment long known and published was that just ascribed to Mr. Aston Key; he had himself, some sessions since, brought under the notice of the Society some cases treated by an application of the subcutaneous section—an operation which, he believed, it was generally agreed on, was one of the simplest and safest. But this and the operations of simple incision, seton, &c., were applicable only to cases in which thickening or hypertrophy of the sac had not proceeded to any great extent. But in the case under discussion (Dr. Hargrave's) there was not mere thickening of the sac, but an almost solid tumour, a mass of adventitious growth situated behind the patellar bursa in which the fluid was originally contained. Complete extirpation of the mass then, he contends, was the obvious course to pursue in such a a case.

Mr. Thorpe begged to add a remark to what had been stated by Mr. Gordon respecting Mr. Adams' cases, namely, their having been dressed from the bottom with lint, thereby exciting suppuration in the sac. In reference to the question of partial or complete excision of the sac, Mr. Adams had stated his objections to the latter mode of proceeding to consist in a dread of opening the joint while detaching the sac from its connections with the ligamentum patellæ, extensor tendons, &c.

Dr. Williams felt that it was entirely out of the question to allude, in Mr. Adams' absence, to any opinions that might have been expressed by that gentleman; but as to the abstract fact of the danger of opening the articulation, he could not for his own part admit it; he could, in proof of the perfect safety of the operation, bring forward the concurrent testimony of two cases so treated at the City of Dublin Hospital by himself. The leading point in performing the operation was, he showed, to cut down on the edge of the patella. The presence of the concrete bodies sometimes met with does not, Dr. Williams states, interfere with adhesions when the opposed surfaces are brought into contact after the operation of puncture or subcutaneous incision.

Dr. Geoghegan exhibited a preparation of diseased bursa, removed by him some time ago from a middle-aged man, occupied as stoker to a steam-engine. The tumour, about the size of a walnut, having rather a solid and somewhat irregular feel, indicative of thickening of the sac, Dr. Geoghegan deemed excision the most suitable procedure. From the inner surface of the sac, a number of finger-like bodies projected, some of them half an inch in length, of a greyish-white colour, elastic, and of cartilaginous consistence, the free extremities being rounded; numerous small circular plates of a similar texture were also observed, some attached by a portion of their circumference, others going loose in the cavity of the bursa.

The present case appeared to Dr. Geoghegan to indicate that those loose bodies, although evidently detached from the interior of the sac, are not always formed in the manner described by Sir B. Brodie, viz., by effusion of lymph on the lining membrane; but, in some instances, rather by distinct growths which, from their length or the narrowness of attachment, become liable to separation by the action of external mechanical influences.

At the conclusion of the discussion, the frequent occurrence of dangerous symptoms, consequent upon even the simplest operations in these cases, was dwelt upon, and some cases alluded to in which, after the failure of various counter-irritants, the external application of nit. argent. was attended with success.

GOSSIP OF THE WEEK.

Apothecaries' Hall.—The following gentlemen were admitted licentiates on the 9th of April, 1846.—Osmond Mullett, William Lord Grundy, Henry James Wordsworth Welch, Edward Bennion Batten, Thomas James, John Yeoman, Octavius Edward Peddle Chard, Bryan Lister, John Barrett Collyns, and William Haines.—16th April, 1846: George Peskett, Henry Peskett, Philip Beal, William Smith, Allan Cleland, George Henry King, Charles Mathias, William James Kite, and William Bowden.

Royal College of Surgeons in England.—The following gentlemen were admitted Fellows of this College, on the 16th inst., viz.—John Nottingham, Liverpool; Caleb Burrell Rose, Swaffham, Norfolk; George David Pollock, Sackville-street; Henry Burford Norman, Duchess-street, Portland-place; Hugh Bell, Yarmouth. The following gentlemen were admitted members on the 17th inst.— J. R. Reece, A. Halley, J. Brady, F. F. Allen, A. McMahon, E. L. West, D. L. Morgan, F. G. Broxholm, A. G. Fenwick, W. C. Tucker, C. Broughton, and W. Delpratt.

Appointments.—Dr. Bence Jones has just been appointed physician to St. George's Hospital. Dr. J. Snow is appointed Lecturer on Medical Jurisprudence in the Aldersgate-street School of Medicine.

Births and Deaths in the Metropolis.—From the weekly report of the Registrar General ending April 18th, it appears that the number of births registered in that time, amounted to 710 males, and 702 females—total 1412. The number of deaths registered in the week amounted to, males 516—females 451, total 967; showing a weekly average derived from deaths during 1841-2-3-4 and 5, and corrected for increase of population to the middle of 1846, of

	IN FIVE SPRINGS.	FIVE YEARS.
Males	456	493
Females........	436	475
Total—	892	968

The deaths registered in this the third week of the second quarter, and in each of the corresponding weeks of the same quarter of the six preceding years were as follows, viz.: in (1840) 888, (1841) 906, (1842) 809, (1843) 961, (1844) 846, (1845) 928, and in (1846) 967, being an average in the series of weeks, exclusive of the last, of 889.

Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity.—The annual dinner of this society took place last Saturday, the 18th instant, at the Freemason's Tavern, and was attended by about sixty of the members and their friends. Sir Charles M. Clarke Bart, the chairman, in proposing the health of the vice-patrons, paid a hearty tribute of respect to the memory of Dr. Denman, one of the founders, if not *the* founder of the Society, and the father of the present Lord Chief Justice Denman, whose election as a vice-patron had recently taken place. The proceedings of the evening (the dinner inclusive) went off with great spirit, and several donations were announced.

Appointments. — Assistant-surgeons: F. W. Blake (additional), to the Caledonia, for service of Plymouth Hospital; W. R. E. Smart, to the Trafalgar; A. Emslie, to Melville Hospital; A Brown, to the William and Mary; A. Jackson (additional), to the Victory; C. Roberts, to the Pique; Francis M'Aree (acting), of the Vindictive, to the Hyacinth; Alfred Jackson (acting), from the Victory, to Haslar Hospital; A. Lillie, to the Griffon. 8th Foot: Assistant-surgeon Henry Clinton Martin, from the 87th Foot, to be assistant-surgeon, vice Johnstone, who exchanges. 39th Foot: Assistant-surgeon Charles Frederick Stephenson, M.D., from the 50th Foot, to be assistant surgeon, vice Stowart, who exchanges. 50th Foot: Assistant-surgeon Ludovick Charles Stewart, from the 39th Foot, to be assistant-surgeon, vice Stephenson, who exchanges. 87th Foot: assistant-surgeon William Smellie Johnstone, M D., from the 8th Foot, to be assistant-surgeon vice Martin, who exchanges.

Haslar Hospital.—Sir William Burnett, M.D., F R.S. and Director General of the Medical Department of the Navy, has just left town on a visit of inspection to this Institution.

The Queen's College Birmingham.—The Reverend Dr. Warneford has presented through William Sands Cox Esq., the munificent sum of £1000 towards the erection of additional rooms for the students, halls of study, lecture-room and chemical laboratory.

By an order in Council, Joseph Henry Green, Esq. of St. Thomas' Hospital, and a member of the Council of the Royal College of Surgeons, has just been appointed one of the Commissioners for the government of the Pentonville prison, in the vacancy occasioned by the resignation of his Grace the Duke of Richmond.

MORTALITY TABLE,

For the week ending April 11, 1846.

Causes of Death	Total.	Average of 5 summers	Average of 5 years
All Causes . . .	967	892	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	155	162	188
Sporadic Diseases—			
Dropsy, Cancer, and other Diseases of uncertain or variable Seat . . .	84	98	104
Diseases of the Brain, Spinal Marrow, Nerves, & Senses	161	155	157
Diseases of the Lungs, and of the other Organs of Respiration	318	271	294
Diseases of the Heart and Blood-vessels . . .	30	26	27
Diseases of the Stomach, Liver, and other Organs of Digestion . . .	93	65	72

THE MEDICAL TIMES.

No. 344. **SUMMARY.** MAY 2.

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

[From our own Correspondent.]

ACADEMY OF SCIENCES.

Meeting of the 20th April, 1846; M. MATHIEU in the Chair.

A new compound of iodine, mercury, and chlorine, recommended in the treatment of scrofula by Dr. Rochard, has proved, according to his assertion, successful in five cases which have lately come under his notice, and in which the external use of the medicine was continued for the space of eleven months. The cases consisted chiefly in white swellings, fistulous ulcers, and enlargement of lymphatic glands. The new compound is called by Mr. Boutigny, iodhydrargyrite de chlorure mercureuse.

ACADEMY OF MEDICINE.

Meeting of April 21st, 1846; Dr. ROCHE in the Chair.

AMPUTATION AT THE ANCLE; BY DR. MALGAIGNE.—A letter was read from Dr. Malgaigne communicating the result of his researches on an interesting point of operative surgery. In diseases of the foot requiring amputation, it not unfrequently occurs that the astragalus remains healthy, and its preservation may be desirable on account of the greater length which will be left to the extremity. No rules have hitherto been laid down for the operation in the calceo-astragalean joint, and M. Malgaigne has endeavoured to supply the deficiency. We will add that no surgeon is better calculated to do so than the talented author of the "Manuel de Médecine Opératoire." Dr. Malgaigne describes at length the various details of the operation, the two difficulties of which were, in the first place, the formation of a proper flap, and, in the second, the ready separation of two bones so closely connected as the astragalus and os calcis. The flap is taken from the internal part of the foot, a semi-circular incision dividing first the tendo Achillis, the skin below the external malleolus, and the dorsal aspect of the foot. The two extremities of this first division are united by the branches of a rounded V, the angle of which descends so low as the middle of the plantar aspect of the foot. A flap is thus obtained of sufficient dimensions to cover the stump, and endowed with a satisfactory degree of vitality. The disarticulation is performed in the following manner:—The articulation of the scaphoid and astragalus being freely laid open, and the tendons cut across, the blade is presented horizontally (the cutting edge towards the joint), to the small anterior articulation of the os calcis, between the surfaces of which it is easily insinuated. The section of the first fibres of the interosseous ligament causes at once a separation of the bones, and the operation is achieved without difficulty.

TREATMENT OF OBLITERATION OF THE PUPIL (ATRESIA IRIDIS), BY THE RESTORATION OF THE NATURAL APERTURE OF THE MEMBRANE; BY DR. ROBERT.—The restoration of the natural pupil was first instituted by Woodhouse, and Dr. Robert is of opinion that the operation does not deserve the oblivion into which it has been allowed to fall. When it is practicable the eye is generally found in the following condition:—The aperture of the pupil is extremely contracted, being sometimes almost effaced, and indicated only by a greyish depression on the anterior aspect of the iris; false membranes, varying in colour from an opaline hue to a dead white occupy its place, and present sometimes a degree of consistency, which may be compared to that of fibrous or even fibro-cartilaginous structures. The circumference of these false membranes—this is an important remark—may be detached *without laceration* from the edge of the pupil, particularly from its inner half. The capsule of the crystalline lens in many cases remains transparent—a fact of which no absolute certainty can be obtained before operation, except when vision is to a certain extent preserved. The capsule may adhere to the false membranes. The tissue of the iris is also found to have undergone more or less alteration, being generally thinned near its aperture by the long continuance of disease. Woodhouse operated with a cataract needle introduced into the eye through the tunica sclerotica, and carried behind the iris towards the pupil, where it was made to lacerate the obliterating false membranes. When, on the contrary, the iris adhered to the cornea, the instrument was carried through the latter membrane. In order to appreciate properly the various modes of operation, Dr. Robert considers atresia according as it has resulted from cataract or not. 1. In the first supposition, when a cataract has previously existed, and has been couched or extracted, the surgeon has not to think of the cristalline lens, and may at will introduce his instruments through the sclerotica or cornea. 2. When the lens is known to be placed behind the false membranes, which obstruct the pupil, Dr. Robert lays down the precept to avoid injuring it—an accident which is inevitable in Woodhouse's operation. Dr. Robert proceeds in the following manner:—The cornea is divided by a narrow puncture, as far as possible from its centre, and in its external part, except when that precise spot is the seat of adhesions with the iris; through the incision a minute forceps, or a small hook, are introduced, in order to seize and detach the false membranes. Two patients have already been successfully operated on by this method; in one case both eyes were blind; and both patients have recovered their sight.

M. Piorry then read a report on a paper treating of palpitations of the heart. The author of the paper referred palpitation in *all* cases to the presence of carditis—a theory inadmissible in the present state of science. The conclusions taken by the learned reporter were unfavourable.

Professor Piorry read a second report on a case of wound of the spleen made with the trocar during the operation of paracentesis abdominis. The case was one of ascites, brought on by a long continuance of ague in a child, aged twelve years. Paracentesis was performed by a pupil, and percussion not having been previously had recourse to, the instrument penetrated eighteen lines into the spleen. Hemorrhage supervened, which fortunately was not fatal, and a long time after death was the result of a disease of the intestines. The intestinal duct was found to be covered with tubercular productions, and a large quantity of blood filled its cavity. Professor Piorry thought this was a favourable opportunity to state that, in his practice, he had often seen ascites the result of the enlargement of the spleen from intermittent fever, absorbed by the exhibition of the sulphate of quinine, and to insist upon the indispensable necessity of ascertaining, before the performance of paracentesis, and by plessimetric percussion, the exact spot of the abdomen in which the viscera or the accumulation of fluid is to be met with, in order to avoid the former, whilst withdrawing the latter. The conclusions proposed by the learned reporter, favourable to the memorialist, were adopted unanimously by the Academy.

Professor Piorry read a third report on a case of "Intermittent Ileus," by Dr. Bouillon-Lagrange. The case was that of a robust countrywoman, aged forty, the mother of five children, who was suddenly seized with violent pain in the right side of the abdomen, nausea, and afterwards incessant vomiting. A tumour of the size of an orange, sensitive on pressure, could be readily distinguished by manual exploration. These symptoms lasted during fifteen hours; subsided, and were, during the next ten days, reproduced regularly every forty-eight hours. Sulphate of quinine, in combination with opium, was exhibited with perfect success. This case, which Dr. Bouillon-Lagrange considers, with reason, to be of extremely rare occurrence, he denominates "intermittent ileus." The word ileus, Professor Piorry conceives to be one of those comprehensive, but unintelligible, designations which should be banished from the medical vocabulary. Prof. Piorry observed two cases in which ileus was said to exist: the first was a case of obstinate vomiting, combined with abdominal pain, Death showed gangrenous spots in the small intestine. This supposed ileus was perhaps a case of poisoning. The other case had more analogy with Dr. Bouillon-Lagrange's observations; plessimetric percussion demonstrated the presence of air in the abdominal tumours; which Professor Piorry attributed to a temporary obliteration of the intestine by spasmodic contraction, and accumulation of gaseous products above the obstruction. M. Piorry concluded by remarking that such accidents were far from uncommon in hysterical patients, and that bark had much more power against them than preparations of opium. The report was adopted.

The meeting adjourned at five o'clock.

HOSPITAL NECKER.

CLINICAL LECTURE. *Diagnosis of Meningitis*: By PROFESSOR TROUSSEAU.

In one of the cases of meningitis towards which we have lately directed your attention, you observed, Gentlemen, that although the child lived twelve days without taking a single particle of food, it

did not grow thin. This is a very remarkable peculiarity of acute cerebral affection of infants. You are aware of the extreme rapidity with which an infant loses flesh in acute pulmonary and abdominal diseases; and the exception to be made in this respect in favour of brain-fever becomes, therefore, in doubtful cases, a useful element of diagnosis. Some days since, I was called upon to visit a child, aged five years, who was suffering from sickness and vomiting. The pulse was quick; the skin hot; the eyes bright; and the outward appearance much agitated. The little patient had, besides, a slight cough, but no stethoscopic sign indicated thoracic disease. All these symptoms might have, therefore, induced us to admit the presence of meningitis, had not the malady lasted three days, during which the child had certainly lost flesh; founding our negative diagnosis on this symptom, we asserted that brain-fever or meningitis did not exist, and the next morning we succeeded in finding in the lung the physical signs of pneumonia. There is something truly remarkable, Gentleman, in this fact of the preservation of embonpoint in meningitis. We do not well see how it can be reconciled with a pulse maintaining itself at 200, for eight or ten days, and with the total absence of food. It is only one proof more of the rupture of the connecting link of the various functions in acute meningitis.

Chronic Hydrocephalus.—You have seen in the wards, a large flabby infant, aged five months, presenting the outward appearances of health, and affected to a considerable extent with chronic hydrocephalus. The effusion of serum in the ventricular cavities is evidently very abundant; the skin of the head is dragged, and displaced by distension to that degree that the brows are carried much above the orbit, whilst the eyeball is concealed in a great measure under the inferior eyelid. We are about trying active treatment in this case, and will, therefore, make some few remarks on the pathology of this generally fatal disease.

What is chronic hydrocephalus?—it is probably a modification of the nutrition of the ventricles of the brain, by which their secreting powers are increased, inflammation having, according to all probability, little or nothing to do with the production of the complaint. We have observed lately a case which would lead us to divide the subject into external and internal hydrocephalus. A child was brought to hospital with an immense accumulation of serum under the pericranium, the bones being perfectly solid and well united. Other cases of a similar nature have been recorded, and they present at first sight some analogy of appearance with internal hydrocephalus, from which they must be carefully distinguished. The origin of these external cysts it is not very difficult to trace; for the most part they are due to fresh irritation having set in, in the cysts of cephalhæmatoma, a fact observed frequently in the hematic cysts of the breast and ovary. Internal hydrocephalus appears to be only the exaggeration of a natural secretion; but almost all the cases die of apoplectic or epileptic accidents—of meningitis, and sometimes of rupture of the basis of the cranium from extreme distension. It is very important to distinguish hydrocephalus from macrocephalia (Heaven forgive us the word), or exaggerated development of the brain. You will observe in ricketty children the head to be very large, and the intellect well developed; the degree of intelligence does not permit us to believe that in such cases the increased size is due to the presence of water, and post-mortem examination has in no instance of the kind shown any cephalic alteration. We conceive that the development of the brain beyond its usual size is here due to the softened condition of the bones, observable in those of the skull, as well as in the limbs. The diagnosis between what I am compelled, notwithstanding my distaste for new words, to call macrocephalia, and hydrocephalus, rests chiefly upon two points—the age of the child, and the state of the osseous system. Hydrocephalus is a disease of the very first infancy, and is seldom if ever observed to begin after the fifth or sixth month of life; the limbs are straight, and the child healthy; in exaggerated development of the brain, on the contrary, the malady never is observed before the second year, because that is also the period at which rickets are found to begin; a coincidence amply demonstrated by inspection of the limbs. The prognosis of hydrocephalus is always a sad one; and the treatment proposed against it, although extremely varied, has been constantly unsuccessful. Calomel in small doses, blisters to the head, tincture of iodine externally, purgatives, diuretics, all the various instruments of therapeutics, have been tried in their turn, and all have proved equally unavailable. Puncture of the membranes has been frequently essayed; in some cases it has been repeated two, three, and four times, without any other result than that of prolonging life for some few months. Compression also has been recommended, but requires much prudence in its application; in proof of this assertion I will only record one instance:—I was consulted some time since for a case of chronic hydrocephalus, and compression was the plan I advocated. Straps of adhesive plaster were fixed round the head, and we were rejoiced to find, after one month, that the head had not increased in size. Some days later, the child lost through his nose an immense quantity of serum, and died suddenly. The bones at the base of the skull had been disarticulated by the water, which had met with an unyielding resistance in the strips of plaster. This fact has rendered us very circumspect in the employment of compression in such cases, and we use it only with great caution. In the patient at present in the wards, we will combine its use with the cap-plaster (*emplâtre à la calotte*), from the resolutive properties of which we may obtain some benefit. This plaster is composed of white and black pitch, vinegar, and flour. No salts of copper are contained in the plaster used in hospital. We conceive that these local applications will be assisted in their action by the exhibition of a strong infusion of digitalis, and of one-tenth of a grain of calomel, daily.

LA CHARITE.

CLINICAL LECTURE.—*Diagnosis of Chronic Articular Disease*; By PROFESSOR VELPEAU.

You have observed in the wards three patients affected with diseases of the knee-joint, which it is not uninteresting to put side by side, in order to demonstrate the practical importance of a precise diagnosis. One of these patients is a man lying at No. 38. His sufferings began in the groin, whence they extended to the knee. The diseased joint is deformed, and increased in size one-third; no fluid is effused in the joint, it is evidently an affection of the synovial and bony structures. The next patient is a woman, whose knee has been enlarged two years; once already, under the influence of hospital treatment, she was almost cured, when a fall occasioned a relapse. The diseased knee is twice the size of the healthy one; about four ounces of fluid are contained in the joint, which cannot be moved without pain. The third case is that of a woman, who suffered some years since of swelling of the joint, and who had been quite free from morbid symptoms down to the last ten days; on the forearm of this patient are scars indicating ancient disease of the bones. The knee is increased in size, and one week was sufficient for the development of the malady without any considerable amount of pain. We find here the external appearances analogous to those of the last stage of white swellings, and a relaxation of the fibrous structures which does not exist in the other two cases, and which is generally met with only after long continued articular disease. The woman is very dull, and possibly the knee has suffered for a longer time than she acknowledges.

A great division of arthropathic affections is that which refers to their anatomical seat in the hard or soft parts. This division is not only warranted by a considerable difference in the prognosis and treatment of both orders of diseases, but also by well-marked diagnostic signs. Thus, when the malady has begun in the hard structures, pain has been the first symptom experienced, and swelling has occurred only much later, the progress is slow, and an internal cause, more or less easy of detection, always governs it; the groin is deep-seated, and presents intervals of exacerbation and of diminution; the swelling, occupying at first only a very limited space of the joint, causes gradual deformation of its shape; all these characters exist in the first case we described to you, of the man lying at No. 38. Articular disease, seated in the soft structures, may be occasioned by external or internal causes. In this form of white swelling we again find signs which can readily permit us to detect the nature and seat of the malady. Thus, the cause itself may indicate disease of the bones or disease of the soft parts: scrofula and syphilis pointing to the former, rheumatism, on the contrary, to the latter. Besides, the swelling is the first symptom observed, and affords strong presumption, when it is followed by, and has not succeeded pain, that the injury has originated in the soft textures. The disease, however, being one of long duration, it not unfrequently happens that it is impossible to obtain from the patient any very certain account of the first stages of the malady, and his want of memory may cause to the surgeon some degree of uncertainty. In most instances, however, it is possible to establish the diagnosis; thus, in our second patient the articular swelling was preceded by a fall; the tumefaction is considerable, and formed in a few hours; no fracture, no dislocation is present—how can we doubt that here the soft parts alone are concerned? The third case is one of a more complicated nature. The patient assumes that the swelling preceded the pain, but we have stated our reasons for receiving his assertions with some degree of doubt. The liquid contained in the joint must be either pus or synovia; because the collection of matter has formed gradually, we are inclined to admit the purulent nature of the fluid—a circumstance which adds to the gravity of the case.

DAN. M'CARTHY, D.M.P.

Italy.

CRETINISM.—M. Garbiglietti, in the *Giornale delle Scienze Mediche della Societa Medico-Chirurgica di Torino*, considers the absence of light as one of the principal causes of cretinism. He remarks that cretinism prevails in deep vallies and narrow gorges, and many of the vallies are so situated as to receive the direct rays of the sun during a few hours only in each day, and its light sometimes reaches them only by reflection. Many places in the mountains, with a northern aspect, are, in winter time, four, five, and six months together without the benefit of the sun's light. The form, texture, aspect, and blackish colour of the schistous rocks are also less available than the calcareous rocks in reflecting the luminous rays.

POLYDIPSIA.—M. Novellis, in the *Giornale delle Scienze Mediche della Societa Medico-Chirurgica di Torino*, describes a case of polydipsia, in which the patient, a male, drank daily the enormous quantity of 480 Piedmont ounces of fluid, and ate in proportion. The quantity of urine passed was always less than that of the fluid imbibed. There was not any evidence of inflammatory action in any of the organs, nor were there any signs of diabetes. The man appeared, on the contrary, to be in very good health. M. Novellis commenced the treatment of the case by placing his patient on animal diet. At that time he ate daily from six to seven pounds of either bread, meat, or eggs, and drank from forty-one to forty-three pints of water, mixed with wine or vinegar. He passed during the same time from twenty-seven to thirty pints of urine. There not occurring any change from this plan, it was next attempted to induce salivation by causing the patient to chew certain roots, and to keep a small stone constantly in his mouth. This plan also proving ineffectual, he was then subjected to vegetable diet, after fourteen days of which, his daily rations consisted of six pounds of bread, spinach, and potatoes, and seventeen pints of wine, water, and vinegar. Urine passed, fifteen pints. After the lapse of another fortnight, his daily diet was six pounds of solid food, and thirteen and a-half pints of drink; urine, eleven pints. The patient appeared to be in much better spirits, and was free from his intolerable thirst. The treatment was then suspended for a week in consequence of an attack of diarrhœa. It was afterwards resumed, the man being allowed a little animal food, and mineral lemonade. Two drops of creosote in eight ounces of barley water were also given, by the advice of M. Cornelianì. The quantity of drink taken was thus reduced to

six or eight pints in the course of four and twenty hours, and the patient continuing in that state for several weeks, he was discharged cured, according to the report of M. Novellis, of the polydipsia.

PELLAGRA IN ITALY.—M. Balardini, in an article published in the *Annali Universali di Medicina*, appears to attribute the occurrence of this disease to the constant use of maize or Indian corn, as an article of diet. He considers that this disease broke out in Italy either concurrently with, or very soon after, the introduction and general use of maize as food. Pellagra, he says, occurs exclusively in the provinces of upper Italy, where Indian corn forms the principal, and, in some instances, the only article of diet used. It does not occur in one province of Southern Italy, the Valtedine, where the other hygiênic causes to which the disease has been attributed, are known to prevail—viz., poverty, atmospheric variations, irrigations, &c.; in that province maize is used with moderation. The disease spares persons in moderate circumstances—inhabitants of towns—who make use of other articles of food, as well as the maize. Abstinence from the exclusive use of Indian corn diet is sufficient to cure pellagra in those persons in whom the organic tissues are not too deeply diseased. The principal and most frequent cause of pellagra is a diseased state of the grain, caused by imperfect maturity. It generally occurs in wet and cold seasons, at which time more cases of pellagra are observed, and the cases already in existence are aggravated. The disease in the grain, consisting in the presence of a fungous parasite, modifies its physical and chemical properties, render it acrid, and apt to produce a special form of disease in the human organism. Two distinct effects, equally injurious, result from this altered condition of the grain. In the first its edible portion is rendered less adapted for nutrition and the reparation of the strength of the frame, so that men and animals fed exclusively on it, become emaciated, and perish slowly. In the second place, the grain thus degenerated, contains besides certain acrid, inassimilable principles, which are absolutely deleterious, and capable of exerting an injurious action on the economy. When thus spoiled, the grain falls in price, and is principally consumed by the very poor—that is to say, the labourers. M. Balardini does not recommend the entire abandonment of maize as an article of diet. In itself, and eaten moderately, it is no way dangerous; but he says it should not be used exclusively, and not at all when in a diseased state. In conclusion, to demonstrate the extent of the ravages of this fearful plague, he states that in the year 1830, in the provinces of Milan, Mantua, Brescia, Bergamo, Como, Pavia, Cremona, Lodi, and Soudrio, out of a population of 1,446,702 souls, there were 20,202 cases of pellagra.

SORE NIPPLES.—M. Rossi, in the *Annali Universali de Medicina*, refers the occurrence of fissures and ulceration of the nipples of newly delivered women, to the presence of inflammation or ulceration, and not unfrequently aphthæ in the mucous membrane of the mouth of the infant, and, as prophylactic of the fissured nipples, he recommends the exhibition of mild purgatives to the infant, and the frequent washing its mouth with barley water and mel-rosæ, or a little vinegar, each time before it takes the breast especially. The nipple also, he says, should be anointed on each occasion with the oil of sweet almonds, or with fresh butter, and washed, after suckling, with barley, acidulated, or bran water. These precautions should never be omitted, as, by a single neglect, the fissured state of the nipple may be induced.

VACCINATION.—M. Calosi, in the *Bulletina della Scienze Mediche*, states that in no one case out of 402 children vaccinated since 1839 at the hospital for orphans, at Bigalis, has small-pox, or any of the diseases consecutive to vaccination, appeared. His statement is the more valuable, as the children being always under his care, its correctness may be fully relied on.

FRICTIONS WITH LARD AS A FEBRIFUGE.—M. Brunetta, in the *Memoriale della Medicina Contemporanea*, details twelve cases in which he employed general frictions all over the body with lard in cases of intermittents, with the effect of curing the disease. It is not impossible that the extensive friction thus practised may have been itself exceedingly influential in arresting the disease.

EPILEPSY CURED BY THE TREPHINE.—In *Il Filiatre Sebezio*, M. Spinelli describes the case of a youth, fifteen years of age, subject to epilepsy from a month after birth, and which was referred to a slight contusion on the right parietal bone received during labour. The patient's head was exceedingly small, and M. Spinelli is of opinion that the brain being compressed by the narrowness of the cranium was the cause of the attacks. In January, 1844, the youth had the occipital bone fractured by a blow, for the relief of which the trephine was applied, and the depressed portions of bone raised. The case was under treatment rather more than a month. The fractured portion of bone was permanently elevated by the brain, in spite of the measures adopted to prevent it, but no inconvenience resulted to the patient, who, at the date of the report, March, 1845, had not had any more epileptic fits.

TŒNIA EXPELLED BY CICUTA.—M. Maulucci narrates, in *Il Filiatre Sebezio*, two cases in which the expulsion of tœnia was obtained by means of the internal use of cicuta, after the pomegranate and other anthelmintics had previously failed. In the first case the remedy was used accidentally, and induced symptoms of its toxic agency.

England.

THE PURGING CROTON.—Under this title Mr. Morton has published a paper in the *Veterinary Record*, on the seeds and oil of croton tiglium, and their action on horses and cattle. He remarks that an objection has been raised by veterinary surgeons to the use of croton from its irritating and inflaming the mucous surfaces over which it may pass or come into contact. This is seen when the expedient is had recourse to of giving the bruised seeds, or the farinaceous residuum after their expression, in the animal's provender, or by dropping the oil on the tongue. Yet on this its operation as a purgative principle depends. When externally applied, some of the preparations of croton prove powerful irritants. A terebinthinate solution of the acrid principle, made by macerating an ounce of the bruised seeds in eight ounces of the oil of turpentine for a fortnight, has been found to be so active as to cause much rubefaction, followed by a vesicular eruption, and even desquamation of the cuticle of the thick skin of the ox tribe. Occasionally this solution requires dilution with olive oil, which is always required for the horse; but for him there are better counter-irritants. The acrid principle is also extracted by alcohol. The form of tincture made by digesting an ounce of the bruised seeds in sixteen ounces of rectified spirit has therefore been recommended. This, on the addition of water, becomes cloudy. The advantage derivable from this pharmaceutical compound is, that in cases of emergency a purgative can be exhibited in the water the animal uses. But, as a purgative to the horse and cattle, the farinaceous matter that remains after croton oil has been expressed from the seeds is by far most generally made use of, it having being found less irritating than the oil, or the seeds themselves; its activity, however, must vary with the amount of acrid principle that remains in combination. The union of this with other cathartic agents renders them more active, while the quantity of each required to be given is lessened. From Mr. Morton's experiments, the cotyledons of the seeds appear to contain the purgative principle. He decorticated sixty grains of croton seeds, carefully separating the testæ and plumulæ, and administered the remaining cotyledons in equal proportions to two aged horses. On the following morning both the horses were labouring under superpurgation, accompanied with much constitutional excitement. The alvine evacuations were profuse, frequent, and watery; the visible mucous membranes highly injected, the extremities and surface of the body cold, the pulse and respiration accelerated, and the prostration of strength extreme. Astringents combined with sedatives were immediately had recourse to, and hot fomentations applied to the abdomen, but all in vain: one of the animals died about mid-day, and the other lingered in great agony till the evening. Inspection of the alimentary canal after death showed the whole of its lining mucous membrane to have been in a state of acute inflammation, the blood-vessels highly turgid, and the large intestines filled with fluid fæces. The cæcum and colon were more particularly involved. The separated plumulæ and testæ were afterwards exhibited to a horse without any visible action on the bowels. The paper is concluded with the details of two cases, in which the exhibition of croton caused death. In the first the croton farina, (quantity unknown) was given in combination with aloes. In an hour's time, the horse purged violently for about twenty minutes: the perspiration rolled off him; the pulse was upwards of 80 beats in the minute, and full; the respiration hurried; the visible mucous membranes highly injected, great restlessness was evinced, the extremities were cold, and the countenance indicated much suffering. Blood-letting was had recourse to, and opium freely administered by the mouth, as well as in the form of enema; hot fomentations were applied to the legs, and heated rugs placed around the body. No abatement of the symptoms appeared to take place, further than a cessation of the alvine evacuations (none having occurred since an hour and a half after the ball was given), but rather an increase in their urgency: the pulse became 100, the restless ness was much greater, and the countenance more anxious. These symptoms continued for a few hours, when the pulse became imperceptible, the body cold and clammy, rigors succeeded, and shortly afterwards death occurred. At the autopsy there was found a slight engorgement in the lungs, but nothing further: not a trace of inflammation could be detected on the peritoneal covering of the intestines, nor on the mucous lining of either the intestines or the stomach, and their contents were in a perfectly healthy state. The other viscera of this cavity were also healthy. In the other instance thirty drops of croton oil were placed on the bit, the animal being very unruly, and it being impossible to exhibit the medicine in any other way. It died in twelve hours, having previously presented symptoms somewhat resembling those noticed in the first case. The owner would not allow the body to be examined after death. Neither of these cases occurred under Mr. Morton's care.

ENLARGED TONSILS IN A BULL.—Mr. Litt describes, in the *Veterinary Record*, the case of a four year old Hereford bull, which had some discharge of a sanious character from the nose, cough, denoting irritation of the larynx, an occasional gasping for breath, and a roaring noise during respiration. There were no appearances of constitutional disturbance; the evacuations were natural; the pulse in no degree disturbed; and the appetite as good as usual. Mr. Litt diagnosed some mechanical obstruction to respiration, the nature of which he could not define. The disease continued to make progress for about two months, when a tumour made its appearance immediately behind the angle of the lower jaw on the left side, apparently deep seated, and very hard to the touch; it rapidly increased in size, until it became as large as a child's head. The disease continued to extend, and ultimately so far involved the pharynx, that deglutition became difficult, and the appetite was lost. The animal was at last destroyed, and on examination there was found situated just above the velum palati a tumour of considerable size, extending in its passage forwards into the chambers of the nose, and thus obstructing respiration, whilst, by its pressure inferiorly on the pharyngeal sac, the passage of aliment must have been rendered extremely difficult. On cutting into it for inspection, the structure of this enormous growth presented no appearance of a malignant character. It seemed to consist simply of an immense enlargement of the tonsil glands, according to the opinion of Mr. Simonds, who looked upon it as most probably the result of catarrh, or subacute inflammation of the tonsils.

(The following are the only articles of interest in the recent number of the *Medical Gazette*.)

EMPYEMA CONSECUTIVE TO PLEURITIS—PARACENTESIS THORACIS.—Dr. Grayling describes the case of a bargeman, fifty-one years of age, who, after the extreme violence of an attack of pleurisy on the left side had been subdued by venesection, leeching, and mercury pushed to ptyalism, presented

symptoms of empyema, for the relief of which paracentesis thoracis was performed, and thirty-six ounces of pus withdrawn. Relief followed the operation, which was repeated in a few days, when only a small quantity of aqueous fluid escaped. After the first operation, tonics and good diet were administered. The second operation was succeeded by increased dulness of the affected side, with hectic and night-sweats; expectoration of a thick, viscid, greenish, muco-purulent fluid, streaked with blood, took place to a large extent, and continued for some time, but gradually diminished in quantity. At the date of the report the patient was entirely free from cough, and had grown quite stout and strong.

STRANGULATED FEMORAL HERNIA.—Mr. Phillips records the case of an old lady, seventy-three years of age, and in infirm general health, who became the subject of femoral hernia. About a year before he saw her, the hernia had become strangulated, and the requisite operation was performed by Sir B. C. Brodie, the recovery being slow, and for some time doubtful. Owing to the low tone of life extensive sloughing took place, but ultimately the recovery was complete, and the patient was able to wear a truss, by which, however, the perfect reduction of the rupture was not maintained. A short time before Mr. Phillips saw her, she being then under Mr. Propert's care, the bowels became obstinately constipated, resisting the action of her ordinary aperients, followed by general tenderness and tympanitis of the abdomen, with vomiting. The symptoms increasing, Mr. Phillips was called in, and on examining the rupture, found that it was apparently easily reduced, leading, therefore, to the belief that the obstruction existed at some point beyond the protrusion. The next day there not being any improvement, but, on the contrary, the hernia being then irreducible, Sir B. C. Brodie was added to the consultation, prior to which the long tube of the stomach pump was apparently passed into the bowel to the extent of twelve or fourteen inches, but the injection returned by the side of the pipe. Another instrument was soon afterwards used in consequence of some imperfection in the other, and the new tube could not be passed into the bowel beyond four or five inches. Sir B. C. Brodie was decidedly against any operation; he did not consider that the intestine was strangulated, the opening having been made so large by operation. He thought, however, that there was obstruction somewhere. The patient died in the course of the night, and the next day the body was examined. The abdominal cavity was laid open by a central longitudinal incision; from this another was carried in an oblique direction so as to lay open the intestine contained in the sac. Although the opening through which the intestine passed was large, it was still small enough to cause a strangulation of the gut, which was of a dark chocolate colour. From that point the intestine was followed until the left lumbar region was reached without the discovery of any obstruction. Mr. Phillips then observed that the tube had passed far beyond that point, and that it was not probable that there was any obstruction further down; however, the search was continued, and it was then discovered that the uterus and the rectum were consolidated into a dense fibrous mass, a small cavity existing in each; that of the rectum being barely sufficient to admit a small bougie. Several curious circumstances are presented in this very interesting case. The almost simultaneous occurrence of a strangulated hernia, and of intestinal obstruction from another cause; as also the ready passage of an elastic gum stomach tube through an obstruction which did not admit of the passage of any fæcal matter, even when acted upon by enemata. The probability is very strong that the intestine would not be strangulated a second time at a point which had been so much enlarged by previous operation; the probability became almost a certainty when the tumour was so readily returned; and yet, although little more than twenty-four hours elapsed, between the gurgling reduction of the gut, and the death of the patient—the powers of life being naturally feeble, yet the intestine had acquired a dark chocolate colour, and had become strangulated at the sidecrural ring. Then with respect to the other obstruction the obscurity is not less:—It existed at a time when the gut very readily passed back through a large opening; it was fair to assume that the obstruction was not there, unless indeed the gut had been nipped or unduly pressed upon by the truss, and had thus undergone contraction; but then the distended transverse colon rendered that view of the case improbable, and made the assumption probable that the obstruction was nearer the rectum than the part contained in the hernial sac; but opposed to that assumption was the fact that twelve inches of stomach pump tube were passed along the intestine with comparative ease; and supposing the rectum disease to be one on which the original obstruction depended, how came it that if it admitted a tube of the size of the little finger, it would not allow fluid fæcal matter to pass? For it is the fact that there was no impaction of solid fæcal matter at any portion of the intestinal tube. Two suggestions here occur; the hernial tumour was very inefficiently maintained by the truss; it was so constantly down that it might have constituted an obstacle, or it might be that the very flexible tube first introduced did not pass through the rectal obstruction at all, but became coiled up in the very extensible rectum of an old woman with very relaxed fibre; for the more unyieling new tube could not be passed beyond four inches. Whatever explanation may be adopted, Mr. Phillips thinks it must be admitted, that whether the rectal disease constituted the original obstruction or not, it is certain that at a later period another was constituted by the strangulated intestine.

LIGATURE OF ARTERIES—Mr. T. Wilkinson King concludes that when an artery has been ligatured, the only essential and real efficient in the closure of the vessel is a thin capsule of cellular membrane—a growth whose arrangement is determined as the vessel retracts, and whose substance, mass, and texture, depend on the state of the natural fluids. This cord formed external to the thread which surrounds the artery, expanding over and sheathing the cones together with continuous attachments, may in fact be traced in part to the walls of an abscess contracting and being stretched. A like cord may form in stumps, if the attachment or adhesion of the tied extremity of the vessel suffice to give, with the arterial diastole, any considerable tensive actions. Considering the cord of the ductus arteriosus which rather grows, and the umbilical arteries which waste much more decidedly, considering such late sequelæ of ligature on an iliac artery as more or less conic arteries, and a cord ten or thirty lines in length, and considering the cord half an inch long, between two healthy and most abruptly contracted arterial ends six weeks after ligature of the femoral, Mr. King thinks there is ample proof that tension is a material and determining element of the process in question beyond what by some will be readily granted. Time and varied illustration, direct experiment or collateral evidence, may yet correct the notions which appear most settled on the subject in hand, and he even anticipates some revolution in the principles now in force relative to ligatures. The healing changes that occur within the tube at the part tied, hardly occupy more space than a mathematical point, for when this point becomes expanded to any extent it is a proof of the deficiency of the so-called internal repair; and the simple fact that the point in question is, for the most part, the only one to which a clot adheres, shows that it alone is altered, if not deficient in organisation. It is a much more positive truism than many seem to suppose, that no agglutination of the living surfaces of the tube can occur where blood intervenes, whether fluid or clot. Again, there is more truth than is very prominent in the assertion, that the part to be healed is but a very small point, and that fortified in a very peculiar manner. The tube is reduced to a cone, and the diastolic pressure within its apex is very inconsiderable, while the sides of the cone have less than their ordinary pressure, more than their usual thickness, and greater support from without by reason of the traction of the ligature. For a given number of days, also, more or less of the contracted vessel is left comparatively undisturbed, to attain a fixed balance between its new circumstances of tension and its consequent modified state of nutrition. All this, of course, is irrespective of adhesion. Still the closure of a great artery by ligature is, indeed, a wonderful process. A little section sloughs, the next surface on each side is absorbed, and the next seems to contract and heal. The last, whether a long or a short portion of the cylinder, becomes conical, or at least rounded. The coagulation of blood is often either questionable or most insignificant. The cord is, in part, a measure of the retraction or separation of the divided ends of the tube. The ultimate contraction of granulation, &c., is a part of the healing process; and when an inch of the tube has sloughed away between ligatures, and the puckering up of a long abscess leaves nothing but a ligamentous cord from one wide empty arterial bulb to another, it is not a little indicative of the importance of external contractions. Occasionally the ligature finally leaves the divided artery with only a solid circular layer of ligament between the two portions of tubes. The retraction of artery in such a case is extremely small, the repair is solid, and after the discharge of knot, a very short cylinder remains, which is concave at both ends, about equal in diameter to the vessel, and formed of threads whose direction is determined by the extensions which operate on each of them. It is by reasons of its shortness and free nutrition that this cylinder does not become narrow towards its middle. It is usually attended by some inflammatory thickening and contraction of the adjacent tube.

Scotland.

EXCISION OF THE HEAD OF THE HUMERUS.—In the *Edinburgh Medical and Surgical Journal*, Dr. Stratton details a case of a severe gun-shot wound of the left arm, by which two inches of the upper part of the humerus were destroyed, and the soft parts much injured. The patient was an Indian boy, six years of age. Dr. Stratton excised the head of the bone, and the boy recovered with an useful limb, after a long convalescence, during which several pieces of bone came away. From the intense heat at the time the accident happened, the wound a day or two after the operation was filled with maggots, which were destroyed by the chloride of lime lotion, and others were not produced.

PULMONARY APOPLEXY.—Dr. Paterson gives at great length in the *Edinburgh Medical and Surgical Journal*, the details of a rare and interesting case of pulmonary apoplexy, proving fatal by rupture of the periphery of the lung, and effusion of blood into the cavity of the pleura. He prefaces the account of his case by a notice of six other cases of the same form of disease which occurred in the practice of other medical men. His patient was a married woman, thirty-seven years of age, the mother of four children, of quiet disposition, temperate and regular habits, and previously always extremely healthy. It appeared that five nights before Dr. Paterson was called in, she had been beaten and kicked violently by her husband, and had from that time complained of severe pain in the right side. When first seen by Dr. Paterson, there was great collapse. The attack came on with violent pain in the right side, so severe as to wake her from sleep. Upon examining the bruised part, no swelling nor discoloration was visible, nor could any fracture be discovered. It was, however, very painful on pressure or the touch. Percussion and auscultation told well for the state of the chest. The heart's action was feeble, and there was a slight cough. The evidence of depression continued throughout the day. The next day there was not any dulness in any part of the chest, but the breathing was rapid, and accompanied with sibilous and mucous rattles; the pulse imperceptible at the wrist, rapid and feeble in the carotids. Two days after, there was a decided dulness in the right side, which continued to increase, until the whole of that side of the chest from below upwards became quite dull. The respiration could be gradually traced leaving the lung as the dulness ascended, until it entirely disappeared from that side. The heart pulsated fully two inches to the left of its proper place. The difficulty of breathing then amounting to absolute orthopnea, paracentesis thoracis was performed, and sixteen ounces of a bloody looking fluid drawn off. No improvement

followed the operation, and the patient died eighteen hours after, eleven days after the sudden seizure, and seventeen from the infliction of the injuries. Just before death, the face was pale, and the lips and nails of a blue colour. The fluid drawn from the chest separated on standing for twelve hours into serum and coagulum, the serum bloody, and the clot dark and soft. There were eleven ounces of serum, and five of coagulum. The body was examined forty-six hours after death. Upon laying open the chest, six imperial pints of bloody fluid were found in the right pleura; it contained no loose coagula, but was thicker at the posterior than at the depending point of the chest. The angle between the diaphragm and costal pleura rising up to the fifth rib was filled by a large black coagulum, and covered over internally with shreds of adventitious membrane. The whole pleura of this side was coated over with this adventitious structure, being thicker and redder, and studded over with bloody papillary elevations, particularly over the ribs anteriorly. No fracture or injury of any of the ribs was discovered. The lung of this side was found diminished to less than a third of its natural bulk, and occupied the superior and posterior part of the pleural sac. It was completely covered over with a layer or layers of adventitious membrane, flocculent on the surface, and stained, like all the rest that was found, of a reddish colour. The texture of the lung was condensed and contained no air; portions of it sank in water. the bronchial tubes were found filled with mucopurulent matter. In the lower lobe of this lung, and to all appearance corresponding to the seat of injury, a tumour of the size of a pigeon's egg was discovered. It occupied the substance of the lower edge of the lung, being covered by pleura and adventitious membrane; upon separating the inflammatory covering from the pleura investing the tumour, it presented an irregularly mamellated form; at one of these raised points, at the outer side of the lung, and very close to the apex, an irregular aperture, sufficient to admit a crowquill, and filled with a coagulum of blood, was discovered. This aperture led to the centre of the tumour, which contained also a firm dark-coloured coagulum. A probe could easily be passed through the aperture to the depth of half an inch or so into this clot. A section of this tumour presented the usual appearance of a mass of pulmonary apoplexy, in the centre of the dark-coloured coagulum, and several smaller around it, which seemed to have caused the mamellated appearance externally; the texture of the rest of the tumour was homogeneous, and of a reddish colour. The left lung was healthy; the bronchial tubes contained a small quantity of purulent looking mucus. The heart was of the usual size, and presented no abnormal appearance. The pericardium, as well as the left pleural sac, contained a small quantity of clear serosity. The abdominal organs were healthy. This interesting case having become the subject of judicial inquiry, the professional opinion given was to the effect that a sufficient connection could not be established between the injuries inflicted by the husband, and the cause of death to tend to his conviction. *** This Scottish opinion if, "not proven," may perhaps have been the most proper under the circumstances, but there can hardly be a moral doubt that the brutal conduct of the husband induced the pulmonary disease which ultimately destroyed his unfortunate wife.

Ireland.

Retroversion of the Uterus.—Dr. Mitchell records, in the *Dublin Hospital Gazette*, the particulars of a case of retroversion of the uterus, caused by a kick inflicted on the patient when between the third and fourth month of utero-gestation. The day after the injury she was unable to pass water; she had a dose of oil, which produced an evacuation from the bowels, and a small quantity of urine was passed. On the fourth day she was admitted into the South Eastern Lying-in Hospital, under Dr. Mitchell's care. On examining the abdomen, the bladder was found much distended, the uterus could not be felt, and the patient stated that after the kick she became quite flat, although previously rather large. On examining per vaginam, it was found that the posterior wall of the vagina was prolapsed through the os externum, dragging the rectum distended with fæces, with it; the os uteri was with difficulty reached, and discovered above the pubis. On passing the finger into the rectum, the fundus uteri was felt low down in the vagina, and on a plane inferior to the os. The woman felt as if a great body was forcing through her, with regular bearing down pains, and complained much of a dragging weight in the loins and groins. On feeling for the meatus urinarius not a trace of it could be discovered, owing to its being drawn so much up, the anterior wall of the vagina being put so much on the stretch by the displaced uterus. Dr. Mitchell tried to depress the cervix uteri, by hooking on the two first fingers of the right hand, so as to take off the pressure from the bladder, in the hope that urine would flow out, but unfortunately it could not be moved, although the middle finger of the left hand was introduced into the rectum at the same time, for the purpose of pushing the fundus upwards; he then introduced the two-bladed speculum vaginæ, and after some difficulty succeeded in passing a small gum elastic male catheter into the bladder, by which means he drew off sixty-five ounces of urine, to the great relief of the patient. An enema was then administered, by which the rectum was emptied of its contents, and the prolapsed vagina consequently much diminished in size. Dr. Mitchell then passed the first two fingers into the rectum, and pushed up the fundus uteri, whilst he drew down the cervix with the first two fingers of the right hand hooked upon it in the vagina. After some time and patience, the fundus uteri ascended, and the os was brought directly into the axis of the cavity of the pelvis, being prevented from passing further backwards by the prolapsed condition of the vagina; the woman was then left quiet in bed; and a sedative administered. In a few days all the symptoms of prolapse disappeared, the uterus reassumed its natural position, and the woman was discharged cured. She has since been delivered of a living child. In commenting on this case, Dr. Mitchell observed that prior to attempting to reduce the uterus, it is necessary to evacuate the rectum and bladder, and it sometimes happens that by this alone a cure is effected naturally. It is not, however, in all cases, an easy matter to pass the catheter; by recollecting, however, that the concavity of the urethra looks backwards instead of forwards, and thus, by passing the instrument with its convex side to the pubis, the surgeon will generally succeed. Although the mere raising up of the cervix uteri, as recommended by Baudelocque, will sometimes succeed in causing the urine to flow out without the use of any instrument whatever, still cases have occurred where it was necessary to puncture the bladder as recommended by Sabatier, when it could not be otherwise evacuated, or where it has been found necessary to puncture the uterus, or the membranes of the ovum, or, still more serious, to divide the symphisis pubis, as advised by Gardien. The symptoms should, however, be very urgent indeed, which would induce any one to resort to operations of so formidable a character, and Dr. Mitchell stated that he agreed with Dr. John Clarke in thinking, that any one accustomed to pass the catheter, will succeed with a small flexible one in every case.

Eccentric Hypertrophy of the Heart.—In the *Dublin Hospital Gazette* Dr. Malcolm describes a case of eccentric hypertrophy of the heart complicated with pericarditis. The heart was of twice the usual size, and both ventricles were dilated; adhesions (which, however, were but slight) were universal between the two layers of the pericardium. A distinct membranous excrescence was observed at the edge of the tricuspid valve, and there was opacity of the aortal semilunars. In addition to the above morbid conditions, the bronchial membrane of both lungs was injected and thickened, and adhesive reddish mucus lined it throughout. The pulmonary tissue was generally congested; and at the apex of the left lung, a dense band of coagulable lymph was stretched between the layers of the pleura. The history of the subject of this case was particularly interesting, and may be very briefly stated as follows:—A young man, aged twenty, previously healthy, was attached; after having accidentally fallen into the dock, with very severe inflammatory symptoms of the chest, especially great dyspnœa and pectoral oppression, for which he was repeatedly treated by large and repeated bleedings, blistering, and the administration of tartar emetic. Under this treatment, he received great relief, and was apparently recovering favourably, when the dyspnœa returned, accompanied with œdema of the ancles. Stethoscopic examination indicated pleuritic effusion and bronchitis; and the very short, rough murmur heard with the first sound of the heart (as it eventually turned out) marked the existence of pericarditis. The pulse was 114, and soft and feeble, and there was great wakefulness. In a few days after this report, he was suddenly attacked with the most urgent orthopnœa, and the most extraordinary palpitation of the heart, the pulse amounting to 185! Under the use of large doses of tartar emetic, his pulse fell in twelve hours to 140, and the dyspnœa became much relieved; subsequently the pulse fluctuated between 140 and 120. His respiration continued always about 40, and bronchial and mucous rales pervaded the whole chest, and masked every other sound. On several occasions the pulse became irregular, and it was ever excessively feeble; perspirations very profuse at times; purulent expectoration appeared several days before death, and faintings occurred on several occasions. During this distressing case, one stethoscopic phenomenon was uniformly remarked, viz., a mucous rale, with dulness on percussion, in the left subclavicular region, which may be explained by reference to the postmortem examination. The duration of this case, from the first pulmonary attack to the fatal termination, was twelve weeks. The great interest attached to it consists in the very long period that the patient continued to linger under such intense pericardial inflammation.

ORIGINAL LECTURES.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

By G. J. GUTHRIE, F.R.S., &c.

LECTURE II.

Partial division of arteries; Case of partial section of the brachial artery; Case of ditto in the femoral artery; Wound of a deep-seated artery the cause of extravasation of blood in the cellular structure of the limb, forming a non-pulsating tumour in general; Pulsations of some tumours caused by the impulse given to them as a mass by the artery against which they are lying; The whizzing sound or thrill absent in such cases; The extravasated blood, if it remain fluid, causes suppuration, if coagulated, is absorbed; If it increase in quantity, the wounded artery should be cut down upon, and tied. The external wound in these cases the guide for the incisions in cutting down upon the artery; Distinction between a false aneurism from a wound and from disease; Operation for a false aneurism from a wound; Mr. Keate's case; M. Delpech's case; Professor Petrunti's case; The false aneurism should be laid open as soon as its nature is ascertained; Injury of an artery by external violence; Case of aneurism in the lower part of the thigh from a blow; Inflammation and abscess following an injury to an artery; Diffused aneurism from the same cause; Enlargement of the collateral circulation after ligature of an artery. Two distinct kinds of collateral circulation; Mortification of a limb the result of a sudden injury to an artery, the collateral branches not having time to enlarge; The external iliac ought not to be tied for diffused aneurism in the groin from punctured wound of the femoral artery; Will cause mortification of the limb, or peritoneal inflammation, with the formation of matter behind it, on secondary hemorrhage from the unclosed ends of the artery, or suppuration of the sac; Ligature of the subclavian inapplicable for a wound of the axillary artery; The Hunterian theory of the cure of aneurism totally and utterly inapplicable to the treatment of wounded arteries accompanied by an

open wound; A wounded artery should be secured at the part where it is injured; Case of aneurism in the ham, with an increased number of the collateral branches; Case of wound of the femoral artery by a musket ball; Occurrence of mortification, requiring amputation; Condition of the wounded artery; Case of musket-shot wound of the femoral artery; Fatal mortification; Case of musket-shot wound of the femoral artery and vein; Secondary hemorrhage; Ligature of the wounded vessels; Fatal mortification; Wound of the popliteal artery; Mortification, amputation, death; Wound of femoral artery; Occurrence of mortification ending fatally, from the non-performance of amputation; Wound of the femoral artery; Partial mortification; Occurrence of secondary hemorrhage; Ligature of a large branch of the femoral by mistake; Death; Wound of a branch from the profunda; Improper ligature of the femoral, terminating fatally. Cases of mortification from injury of the popliteal ending fatally while waiting for the line of demarcation; Fatal mortification from arteritis; Case of diffused aneurism from injury of the popliteal, threatening gangrene; Treatment by incisions; Case of ligature of the common iliac for supposed gluteal aneurism; Prevention of mortification by frictions on the limb for twenty-four hours; Conclusions.

When an artery is merely cut or torn half through, but not completely divided in the first instance, it is in the same state with regard to hemorrhage, as if it had partially given way by ulceration. It can neither retract nor contract, and will continue to bleed until it destroys the patient unless pressure be accurately applied, and maintained until further assistance can be procured. The practice to be pursued is to divide the vessel if it be a small one, such as the temporal artery, when it will be enabled to retract and contract; and the bleeding will in general permanently cease under pressure, especially when it can be applied against the bone. If the artery is of a larger class, and continues to bleed, it should be sufficiently exposed by enlarging the wound; a ligature should be applied above and below the opening in the vessel, which may or may not be divided between them at the pleasure of the surgeon.

CASE 11.—During the battle of Talavera, in 1809, a man was brought to me who had lost a large quantity of blood from a wound made by a musket ball in the arm, which had bled profusely, and was only arrested by tying a handkerchief tight over the wound. The brachial artery, just below the edge of the pectoral muscle, had been half cut across, and on being exposed again, bled furiously. A ligature was placed on the artery, above and below the wound, and the man perfectly recovered.

CASE 12.—In June, 1829, I happened to be at Windsor, on a visit to my old friend the late Dr. Fergusson, and was called to a young gentleman, the upper part of whose right femoral artery had been accidentally cut by the point of a scythe. On dilating the wound, a tourniquet being on the limb, black blood flowed freely from it; on unscrewing the tourniquet by degrees, arterial blood showed itself, and the upper end of the artery was secured by ligature when the tourniquet was removed. Venous-looking or black blood then again flowed in greater abundance than before, and evidently from a large vessel. This I restrained by pressure made below the wound with the thumb of the left hand, whilst I laid bare the lower part of the artery, from a slit in which near an inch in length, the black blood was seen to flow. A ligature passed around the vessel below the wound, suppressed the bleeding. The artery was not divided, and the young gentleman perfectly recovered, and has continued well until this day. The absolute necessity for two ligatures was here well shown, as well as the flow of dark coloured blood from the lower end of the artery.

When an artery is wounded at some depth from the surface, and the external opening is small, blood not only issues through the opening, but is often forced into the cellular structure of the limb to a considerable distance, the pulsation of the tumour is observable, and the thrill or sound which accompanies a ruptured artery is distinct. If a large quantity partly in a fluid, partly in a coagulated state, is collected immediately over and around the wound in the artery, the tumour may not pulsate or give forth any sound if the coagulated blood is in considerable quantity, although some elevation of the tumour may be observed corresponding to the pulse.

This rising or pulsation of the swelling often depends on the impulse given to the whole as a mass by the artery against which it is lying, and not upon blood circulating through it. An impulse of this kind is distinguishable in a bronchocele, which lies immediately over and in contact with the carotid artery, and was well shown in two cases which came to me from the country for operation, being supposed to be aneurisms. The mere act of deglutition removed the tumors from the artery, and showed they belonged to the trachea, and not to the vessel, and when elevated, the pulsation was nearly indistinct. It is the same when blood is extravasated by the rupture of small vessels, in consequence of the passage of a wheel over the limb, and especially in the thigh, where I have seen a swelling containing fluid blood pulsate in an almost alarming manner, until it gradually diminished as the blood coagulated, when the motion became a mere elevation at each stroke of the heart. The whizzing sound or thrill attendant on a ruptured artery is in these cases wanting, being a very diagnostic mark of this accident, although I am well aware that where there is true aneurism, and it has burst, forming a diffused and spurious one, the thrill may be wanting, but the history of these cases enables a surgeon to distinguish between them. If several ounces of blood are thrown out, and remain fluid, they ought to be evacuated, or suppuration will ensue. If they become coagulated, the mass will be gradually absorbed. Fluid blood should be evacuated by a small opening, and the part afterwards treated by compress and bandage. If the fluid or partly coagulated blood should increase in quantity, and the swelling continue to enlarge and pulsate, the extension of the mischief should be arrested by opening the swelling and securing the artery by ligature.

When the external opening is enlarged, and the clots which filled it up are at all disturbed, arterial blood begins to flow, and the finger will readily follow the track through which it passes down to the artery, if it should not be too far distant. If the incision is made sufficiently large to enable the operator to remove these clots of blood with rapidity, the finger will more readily pass down to the wound in the artery, which, if a large one, may be thus easily discovered, if within reach and sight, provided the tourniquet be thoroughly unscrewed, and the surgeon is not afraid. A ligature should then be placed above and below the opening in the artery. M. J. Z. Amussat, in a memoir read before the Royal Academy of Sciences, of Paris, in February, 1843, has dwelt at length, on and has attached perhaps more importance to this track leading from the external opening to the wound in the artery, than it appears to deserve. The great merit of his work is, however, the acknowledgment which he thinks it a matter of great importance to make, and which he supposes he has deduced from his own observation, "that the surgeon should take the wound for his guide in all these cases of aneurismal swelling, and follow the conducting canal in the tumour itself down to the wound in the artery, which is to be secured by ligature above and below the opening in it, unless the external wound should be too distant from the course of the vessel." This is a fact worthy of remark, being an acknowledgment of the correctness of those opinions, and of that practice I have promulgated by my writings and lectures since the battle of Albuhera, in 1811.

When an artery is wounded, and the external opening in the integuments heals so as to prevent the blood from issuing through it, a traumatic, spurious, circumscribed, or diffused aneurism is said to form, according to the facility which is offered by the structure of the parts for the confinement or diffusion of the extravasated blood. A traumatic aneurismal tumour of this nature differs essentially from aneurism which has taken place as a consequence of disease, and not of direct injury. If a spurious aneurism forms from disease, the artery is in general unsound for some distance above and below the tumour. In the aneurismal tumour from a wound, the artery is perfectly sound, except as far as concerns the seat of injury. There is then not only a great and essential difference between these two kinds of aneurism as regards their nature, but also with respect to the collateral circulation, and the operation to be performed for their cure; and the surgeon may not overlook these facts.

CASE 13.—A school-boy, about fourteen years of age, let a penknife drop from his hand while sitting down, and drew his knees suddenly towards each other to catch the falling knife; the point was thus forced into the inner and middle part of the thigh, and wounded the femoral artery. The medical man on the spot put a plaster on the little incision in the integuments, and the wound quickly healed. The boy complained of uneasiness, but was supposed to be making more of it than necessary, and was made to go into school as usual. The limb however began to swell, and the boy was brought to London, and consulted his family surgeon, who put him to bed, and poulticed and fomented him, expecting an abscess had formed, which I was sent for to open during his illness. I found the limb very much enlarged from the upper part to the knee, and with that peculiar discoloration which convinced me that blood was under the integuments, and I refused to open it where the abscess was supposed to be pointing, until I had everything ready for the operation of securing an artery. There was no pulsation to be felt when I first saw it, and I was assured there had been none. When all was ready I introduced the point of a lancet, and after a clot of blood had been forced out, a jet of arterial blood flew across the room. The hemorrhage was arrested by pressure below Poupart's ligament, whilst I enlarged the opening in the integuments. Two washhand-basins were filled with coagula, and I put my finger on a large opening in the artery, under which two ligatures were passed by means of an eye-probe, and the artery was divided between them. The muscles had been clearly *dissected*, and the cavity extended from the fork internally, and trochanter externally, to the knee. There was much less suppuration than I expected. The ligatures were detached about the usual time, and the patient entirely recovered. This case was given to me by Mr. Keate, and the following it from *Delpech Clin. Chir.*

CASE 14.—M. Maigret was wounded by a small triangular sword in October, 1816, in the lower part of the left thigh; the anterior wound bled profusely, but the bleeding was arrested by compression, and at the end of eight days both the external wounds had healed. On moving about incautiously he felt pain in the part, and perceived a small tumour under the cicatrix in front, about the size of a nut, and which rapidly increased, so that on the fifteenth day the femoral artery in this case, accompanied by *two* veins, was tied above the edge of the sartorius muscle, by an incision begun three inches below Poupart's ligament. The patient perfectly recovered, although it was a long time before the swelling totally disappeared.

CASE 15.—Raffaele Castaldi, aged thirty-seven, was stabbed, July, 1824, on the external and superior part of the left thigh, and lost a considerable quantity of blood. The wound closed, and at the end of eight days a small, but strongly beating tumour was observed opposite to the cicatrix. The treatment of Valsalva was adopted, and ice and astringents were applied to the swelling. These means were continued until December, and ultimately led to the formation of a deep eschar on the face of the tumour. On the cicatrisation of the ulcer left by this, the swelling was found to be diminished, to be hard, and without pulsation. At the end of a year, believing himself cured, he placed a piece of copper over the firm swelling, by way of protection, and returned to his usual laborious exercises. In November, 1834, twelve years afterwards, on lifting a heavy weight, he felt something give way in the old swelling, which immediately became larger, and beating, and in 20 days extended from one inch below Poupart's ligament to the lower fourth of the thigh. Professor Petrunti applied a ligature immediately below Poupart's ligament, which came away on the thirteenth day. On the thirtieth, the wound was nearly healed. On the thirty-first day,

bleeding took place from the wound, which was restrained by compression, but returned on several occasions. A compress and tourniquet were then fitted on above Poupart's ligament, which succeeded in stopping the hemorrhage, but gave rise to a deep gangrenous eschar, which took a long time to cure. Three months after the operation the wound healed, the tumour gradually diminished, and the patient ultimately recovered.—*Gazette Medicale*, 1835, p. 647.

These three cases show each a different mode of treatment. Mr. Keate, called upon to open an abscess, demurred, doubtful whether he had not a diffused aneurism to deal with. M. Delpech knew he had a diffused aneurism before him, but which was not so large as to preclude his placing a ligature above it, yet below the profunda, on which, he says, he reckoned for the support of the limb. He succeeded, and his operation (of Anel) was admissible because there was no external opening communicating with the sac, and that the blood in it was coagulated. If it had remained partly fluid, partly in clots, suppuration would in all probability have taken place, and a renewal of the bleeding might have occurred, requiring another operation. Mr. Keate's was therefore the safest and the best mode of proceeding, even under the most favourable circumstances. In M. Petrunti's case the tumour was not removed, and the artery yielded after an interval of twelve years from the receipt of the injury, probably from becoming diseased. The operation of Anel failed, when that of Hunter on the external iliac would have been done by all English surgeons, and would have succeeded, inasmuch as there is reason to believe that the upper part of the femoral artery was unsound, and that the compression above the pubis, which gave rise to the deep gangrenous eschar, obliterated the canal of the external iliac artery in a similar manner to the operation.

The great error in all these cases consisted in not laying open the tumour on the eighth or tenth day, whilst it was small, or as soon as its nature was ascertained, and placing a ligature on the artery above and below the wound. If a tumour of this kind, being circumscribed in the first instance, should burst, and blood be in consequence poured out into the cellular membrane of the whole limb, it swells enormously, and gangrene is oftentimes only prevented by amputation. This may occur in a case of true aneurism, and is always a very dangerous accident. If taken in time the ordinary operation for aneurism may suffice, if long-deferred, amputation will be a last but not often a successful resource.

An artery may be injured by external violence without being punctured, and without any external wound, the consequence being the obliteration of the canal, mortification of the extremity, or the formation of an aneurism, which may be a true one by dilatation if the internal coats only are affected, or it may, through ulceration, suppuration, and sloughing, be spurious, and circumscribed, or diffused.

CASE 16.—A stout, young, and healthy man was admitted into the Westminster Hospital with an aneurism of the lower part of the thigh, about the size of a small but flattened orange. Some three months before he had received a sharp blow on this part from the edge of a piece of hard leather, which gave him acute pain for a time, and he some days afterwards discovered the beating swelling for which he was sent to me. A ligature, composed of one thread of strong dentist's silk, placed on the femoral artery in the lower part of the upper third of the thigh, came away on the twelfth day, and the man perfectly recovered. There can be little or no doubt of the aneurism having formed after a partial rupture or derangement of the inner coats, and from a dilatation of the outer coat of the artery.

CASE 17.—A young and healthy man, of a vigorous constitution, was discharged from a cavalry regiment, and sent to me with an aneurism of the thigh, where the artery passes through the triceps. Some weeks previously the horse of another soldier had run against him when on horseback, and forced the end of a hard bolster between the affected thigh and the saddle, giving him acute pain at the part, which subsided into an uneasiness for a day or two, some time after which he discovered a small beating swelling, which gradually enlarged, and prevented his riding, and on account of which he was discharged. I admitted him into the Westminster Hospital, placed a ligature on the femoral artery at the usual place, and he perfectly recovered.

When inflammation and abscess follow an injury inflicted on the artery through violence, without an external opening, or if sloughing should take place, the treatment by incision is absolutely necessary, as well as the application of two ligatures to the artery. When a diffused aneurism forms rapidly in a limb after a great injury, but without an external wound, the place in which the artery or arteries is or are injured being unknown, the case is greatly complicated, and requires the most serious consideration, whether the trunk of the artery shall be tied or the limb be amputated. If signs of mortification occur, the limb should be cut off forthwith.

A correct knowledge of the collateral ciculation is of the utmost importance; surgeons understand by it the means whereby blood is sent to the extreme parts of a body, or to a limb, when the usual supply through the principal trunk is cut off. This collateral circulation is more perfect, more active in young persons during the increase or growth of the body, than it is either at maturity, or in the decline of life. The important point is not, however, alone referrible to the time of life in which the continuity and permeability of the main trunk ceases to exist, but to the nature of the disease or injury which has given rise to it.

When an operation has been successfully performed for aneurism, and the patient has died, some time afterwards dissection has shown various arteries enlarged, both above and below the part where the trunk was obliterated by the ligature; and not only an enlargement of arteries, which from their regularity have received names, but others have been developed not usually known to exist, or not of a size to be conveniently traced. These through their frequent anastomoses bring the blood at last into several larger trunks, by which it is again conveyed to the original vessel below all and every obstruction which may have taken place; thus compensating by a circuitous route for the loss of the direct supply. The principal object of inquiry is, do these vessels always exist, or at what period of time do they begin to enlarge, so as to enable them to carry on the circulation, in the manner in which it is presumed to be done?—for few will assert, that the enlargement of these particular collateral vessels was an accidental play of nature, and existed previously to the commencement of the disease or injury for which the operation was performed. On this point, the theory of the operation for aneurism and its applicability to wounded arteries appears to hinge; and what is of more importance, on which the practice resulting from it depends.

Two distinct kinds of collateral circulation are at present acknowledged: one by direct large communicating vessels; the other through the indirect medium of the capillary arteries, inosculating with each other. Where the direct communicating vessels exist, little subsequent change takes place in them. It is otherwise with the indirect capillary vessels. When the radial or ulnar artery is divided in the hand, the blood will not only flow readily from each end of the divided vessels, but equally red and arterial from both; the communication being through direct arterial branches from one vessel to the other. It will also be red and arterial if the division take place at the wrist; and may be so in the brachial, but if the femoral in the lower part of the thigh be wounded, the colour of the blood issuing from the lower end of the artery, if any issue at all, will be venous. It is so, because it has been obtained from the capillary arteries, which in this case being empty receive blood by regurgitation from the veins, the valves of which when present do not prevent its reflex course. If a limb be injected and carefully dissected four or five days after a ligature has been placed during life high up on the principal trunk, the capillary vessels will be seen to be well injected; but few or none will be found large enough to admit of their inosculation being traced throughout. If another limb be injected and dissected, some sixty days after the ligature had been applied,—and opportunities have occurred of making such dissections in man,—a difference will be distinctly observed between the two preparations. In the latter, the capillaries will not appear to be so fully injected, but several larger and more tortuous vessels will be found in situations where they were not expected to exist; and the anastomoses of these one with another, and generally by arches, may be traced to their communication with the principal trunk, both above and below the obliterated parts. If an incision were made in the nearest pervious portion of the lower part of an artery of a person who had undergone this operation, arterial blood would issue from it. The communication would have become direct by communicating branches, and the capillaries would have returned to their accustomed duties.

During the first twenty-four hours after the division of an artery such as the femoral, or the application of a ligature, the temperature of the limb is commonly diminished; after that period, and as the action of increase takes place, the temperature is usually from three to five degrees higher than in the opposite healthy limb. At the end of from eighteen to twenty-eight days, in a successful case, the temperature is found to be equal in both.

It is asserted by some sanguine supporters of the all-powerful influence of the collateral circulation, that it is sufficient at all times, and under all natural circumstances, to maintain the life of the extremity. The practice of the Peninsular war proved the fallacy of this opinion in too many instances, to admit of any doubt of its inadequacy to do so in the lower extremity after the division of the femoral artery, under ordinary circumstances. The fact of employment or of a new development of vessels having taken place after the commencement of the disease or the reception of the injury has been demonstrated by dissection, and it is through them the life of the limb is to be preserved.

It is most reasonable to conclude, that the collateral branches begin to enlarge shortly after the commencement of the disease, as a part of the curative process which nature endeavours to set up in most instances; the essential points of which are, in an extremity, 1st, the obliteration of the canal of the artery immediately above, and generally below the tumour; 2nd, the coagulation of the blood within it; 3rd, the enlargement of the collateral branches above and below it.

When a limb is lost through mortification, as the consequence of a division or obstruction of the principal artery, it usually takes place after the infliction of a sudden injury, in consequence of the collateral branches not having had time to enlarge.

In my work on injuries of arteries, and in this place, treating of the collateral circulation, I have asked the question:—"If the femoral artery be punctured near the groin, and a diffused aneurism form in a few days, extending up to Poupart's ligament; can the operation of placing a ligature on the external iliac be performed on the same principle, or with the same hope of success, as if the case had been one of true aneurism of several weeks or months' formation? The answer is in the negative. The Hunterian theory of aneurism is not applicable to the case. The surgeon who placed a ligature on the external iliac, under such circumstances, would probably lose his patient from mortification, because the collateral branches would not yet have had time to enlarge." I may now add, if he should escape this danger, there is the risk of inflammation of the peritoneum which has occurred to myself and to several others, and of the formation of matter behind it; or the wounds if not closed may bleed, or the diffused and spurious aneurism may enlarge from blood flowing into it from both ends of the artery, which are not partially closed, as in true aneurism; or it may suppurate, burst, and require in each case another operation, in order to suppress the bleeding. It is an operation which I shall show you cannot be supported on principle, which has not succeeded in practice, and which will be resorted to hereafter only as a last resource, when those means I have pointed out, have unfortunately failed; and when in all probability it will fail also.

The operation for placing a ligature on the subclavian artery, above the clavicle, in a case of wound of the axillary artery in the armpit, is equally inadmissible with that for applying a ligature to the external iliac for a wound of the artery in the groin, and ought alike to be abandoned. These are grave questions which interest the public more

than the profession. They only indirectly affect the anatomist and the surgeon, who does one operation with the same degree of knowledge and ability as the other. To the public, to the sufferer, they are questions of life or death. By that operation, which during the war in the Peninsula was found to be efficient, the sufferer has a fair hope of recovery; after the Hunterian operation, he may live through accidental circumstances only, which may be prayed for, but which can never be honestly and fairly expected. They should never therefore be trusted to, for nothing which is dependent on chance or accident can or ought to become a principle in surgery. The Hunterian theory of the cure of aneurism is totally and utterly inapplicable to the treatment of wounded arteries, accompanied by an open wound, however small or distant. It is always doubtful, and frequently dangerous and destructive even where the external wound has healed. A wounded artery should always be secured at the part where it is injured, and the greater number of those who suffer from such accidents, and are not so treated, will in all probability be lost, unless surgery can come to their assistance by ulterior and more painful operations.

When an aneurismal limb has been injected, on which an operation had not been performed, the collateral vessels have all been found larger and more fully shown than on the opposite side, although not to the same extent as in cases of a similar nature in which the operation had been done.

It is necessary that this enlargement of the collateral branches should take place an early period, because in many cases of aneurism the artery beyond or below the tumour is obliterated long before any operation is performed. The main supply of blood has been already cut off from the extremity, and the operation adds very little to the derangement of the circulation which has for some time taken place below the tumour. The following case shows the increase of collateral vessels so as to double the number on the opposite side.

Case 18.—Alexander M'Donald, 28th regiment, was admitted into Hilsea Depôt Hospital, for a gangrenous spot on the great toe of the right foot, which soon got well. Twelve days after his admission, a pulsating tumour was first observed in the ham of the same side. On the 7th of August the tumour was of the size of an egg, and the arterial action strong in every part of the body. He died suddenly, and on examination the right femoral artery, or of the diseased side, was larger than that of the left. The aneurism was situated exactly at the spot where the popliteal artery divides into the posterior and anterior tibial arteries, and was of the size of a walnut. The posterior tibial opened directly into the sac. The orifice of the anterior tibial artery, which had originally opened into the sac, was closed, as well as about three-eighths of an inch of the vessel. Within the space of six inches above the aneurismal sac, the artery gave off fourteen branches in pairs, larger than those in the opposite limb, which were only seven in number.

These facts appear to me to be conclusive: they show that the collateral circulation is not the same, is not in the same stage of preparation, in a limb suffering from a divided or wounded artery, as in one in which an aneurism has for some time existed; and they also show why mortification is more common after wounded arteries than after operations for aneurism.

Case 19.—Private J. Barnes, 29th Regiment, on the 16th of May, 1811, at the battle of Albuhera, received a musket ball in the right thigh, behind and above the knee, inclining downwards and inwards, close to the condyles of the femur, and in the direction of the femoral artery becoming popliteal; it bled violently at the moment, and so continued for a few minutes, during which time he conceives he lost two quarts of blood. It then ceased, and he was dressed in the usual slight manner, and remained two days upon the field of battle, until removed to Valverde, nine miles, on a bad road, and on men's shoulders, in a blanket converted into a bearer. He was considered as one of the slighter cases, until the gentleman in immediate charge of him requested me to see him, on account of his toes being in a state of mortification.

On the evening of the 3rd of June, eighteen days after the accident, the man was placed on a bullock car, to be removed with the rest of the wounded to Elvas; the mortification of the foot having ceased to increase, and a line of separation having been formed. Shortly after the cars moved, I was informed that he was bleeding from the wound: it evidently appeared to flow from the popliteal artery; and as it issued slowly, I supposed from the lower divided end. The foot being partly lost, I determined on amputation above the knee, which was performed at Olivença. The amputated limb was sent after me to Elvas, that it might be examined at leisure. I carefully traced the course of the wound, and found in it a little coagulated blood, but could not see the mouth of the vessel. A probe passed into the upper end of the artery was obstructed before it reached the ulcerated surface by nearly an inch; and on passing it up the lower one, it was stopped exactly in the middle of the track of the ball, by a veil or substance drawn across the mouth of the vessel, and which, on careful examination, showed the point of the probe at one part of the circle, although too small to let it through; and from this part I conceive the hemorrhage came. The divided ends were one inch apart. The upper, or femoral portion, for near an inch, contained a firm coagulum, filling up that part of the artery which had contracted like the neck of a claret bottle. The lower or popliteal portion of the artery had a very peculiar appearance; the substance drawn across appeared to have closed it completely at one time, and to have given way from the rough motion of the car at the point now open, and which is very small even when the sides of the artery are approximated. A very little soft coagulum was behind it; and if the man had not been removed, the vessel might have remained secure. This case shows very distinctly the means adopted by nature for the suppression of hemorrhage from both ends of a divided artery. The preparations I shall place in the Museum of the College of Surgeons.

Case 20.—In another soldier, under similar circumstances as to the nature of the wound and mortification of the foot; no hemorrhage took place on the journey to Elvas, but the man died three days after of mortification of the leg. He did not remain under my direction at Elvas, and no examination of the limb was made.

Case 21.—Serjeant Baptiste Pontheit, of the French 64th regiment, was wounded by a musket ball at the battle of Albuhera, on the upper and fore part of the thigh, which passed out behind, in the direction of the femoral artery. He lost a great quantity of blood at the time, to the best of his recollection, and the wound went on well until the 26th, ten days after the battle, when he felt something give way in his thigh, and found himself bleeding from the wound, which however soon ceased on pressing his hand upon it. In the afternoon on again moving, he lost about half a pint of florid blood, which induced the surgeon on duty to place a tourniquet on the limb, and inform me of the circumstance. When at leisure (in the course of two hours) I removed the tourniquet, and as no hemorrhage occurred, and there was no swelling in the vicinity of the wound, I replaced the dressing with a precautionary screw tourniquet, explaining to him its use, and the probable nature of his wound, together with the operation requisite to be performed in case of further bleeding.

I should before have mentioned that he was not a strong man, and was exceedingly anxious about his situation, and very restless: on turning at night he lost a little more blood, which ceased by his tightening the tourniquet, which was shortly after loosened. In the morning, every thing being removed, there appeared some swelling about the wound, the opening of which was filled up by a coagulum: gentle pressure being made, it readily turned out, and was followed by a stream of arterial blood, leaving little doubt of the femoral artery being wounded. Compression being made in the groin, I made an incision three inches and a half in length, taking the wound as a central point, and exposed the femoral artery and vein: both were wounded, the former being half destroyed in its circumference, surrounded with coagulated blood, and appearing as if it had sloughed from being touched by the ball, the course of which was directly past it, and I conceive would have carried it away, if it had not been for the elasticity of the artery. A ligature placed above, and another below the wound, secured both artery and vein; the incised wound was brought together by adhesive plaster, and the limb placed in a relaxed position. The operation was of short duration; he lost little or no blood, but the circulation was very languid, and the man exceedingly low. The warmth of the leg and foot was soon below the standard of the other; warm flannels were applied, and some brandy and water was given to him. In the evening the heat was more natural, and the man returned thanks for the humanity and kindness shown to him, congratulating himself and me upon the success of an operation which he had supposed to be infinitely more severe. The next morning he ate a tolerable breakfast, but felt a pricking sensation in the calf of the leg, which was as warm to the hand as the other, but the foot was cold. The second day, the swelling of the limb, its appearance, and discoloration on the under part, indicated approaching mortification, which on the 3rd was evident, and on the 4th at mid day he died, the limb up to the wound being nearly all in a gangrenous state. No adhesion had taken place in the wound, or in the artery, which showed the inner coat cut, the ligatures being firm, and no coagulum behind them. In this case, nature appeared from the first quite unequal to carry on any of the necessary operations; which may have arisen from the very debilitated state of the patient, as well as from the double obstruction to the circulation. He was a very gallant soldier, had been in twenty battles, was to me an object of solicitude, and had every attention it was in my power to bestow. He begged me to keep his watch, and although it is worth nothing, I do keep it as a relic of by-gone days.

Case 22.—Captain St. Pol, of the 7th or Royal Fusiliers, a son of his Majesty Louis Philippe, King of the French, by an English lady, was wounded in the ham from behind, whilst in the ditch at the foot of the great breach at Badajos. He fell instantly, and lost as he thinks, a considerable quantity of blood. On recovering he was raised from the ground, and walked a few paces prior to his being carried to his tent, where I saw him in the afternoon of the next day, the 7th. The leg had ceased to bleed before his arrival in camp. A substance could be felt on the inner side of the patella, which by the sensation communicated to the finger on moving it appeared to be the ball, which was extracted. A small artery was accidentally divided, and some dark-coloured blood also issued from the cavity; the ball was lying loose and unconnected; the finger on being passed into the joint which was swollen, discovered no splinters of bone, and the entrance of the ball behind would not admit the finger. His having walked some distance on the leg, and the absence of any splinters between the articulating extremities of the bones, induced Dr. Armstrong the surgeon of his regiment, and myself to think that the ball had entered with little injury to the bone; and after stating to the patient the little hope we had of ultimately saving the limb, independently of the great danger to which he was exposed, compared to the certainty of the operation of amputation at the moment, to which he would not consent, we assented to his retaining the limb for the present, thinking he would at least get through the inflammatory stage, when the operation could be performed satisfactorily to himself, although under much more unfavorable circumstances. The next day he was removed into Badajos on a litter, the heat of the tent being insupportable.

On the morning of the 9th I saw him early, being a friend in whom I took the greatest interest, when the want of circulation in the foot was evident from its having lost its natural colour and warmth; the knee was swelled, but not painful, and I had no doubt that the artery had been divided by the ball. The marbled appearance and tallow-white colour soon indicated the loss of the leg above the calf; and vesications formed on the foot, already of a green colour.

On the 12th the extent of the gangrene was defined, on the back of the knee up to the original wound, at its lower edge, gradually receding as it advanced to the fore-part of the leg, which for three

inches below the knee was apparently sound; the uneasiness of the knee being moderate, the incised wound looking perfectly healthy, although the latter had not united.

On the 16th the separation of the dead from the living parts having taken place behind, and being well marked and commencing on the fore part, the limb was amputated as low down as possible. Sixteen vessels were tied; the parts were gently brought together, without any hope of union.

On the 18th, there being some swelling of the stump, the strips of plaster were removed, one only remaining as a support to the vessels.

20th. Half the ligatures came away at once, they having gradually formed into two parcels; the stump was quite open, the bone well covered, and good granulations appearing, with a great discharge of well formed matter.

On the 22nd, his want of strength to carry on the necessary actions became apparent.

On the 24th, he died.

On examining the amputated limb, the popliteal nerve was found untouched, the ball having passed on the inside; the popliteal vein was also entire, having a small tumour adhering to its under part between it and the artery, the divided end of which was closed by a yellowish green firm substance, readily distinguishing it from the surrounding parts. On clearing the whole from the bone, and making a small circular opening into the tumour, which was elastic and covered with brown fibrous layers, it proved to be an aneurismal sac, smooth on the inside, containing florid arterial blood, and some little coagula. The cavity of the sac was not perfectly regular, being nearly divided on one side by a process running into it. The artery, on being carefully opened to the closed end, appeared to have been injured above the part divided by the ball, and to communicate with the sac by a small fissure or rupture. The end of the artery was then slit up, so as to show the very little thickness of the closing substance, and the great original contraction of the diameter of the vessel. There was no internal coagulum, neither was there any laid over the external part of the artery; between it and the bone there was a coagulum lying of the size of a small phial cork. Displeased with myself for having listened to Captain St. Pol's petition for delay, which I knew even under more favourable circumstances had been futile, I felt a melancholy satisfaction on viewing the diseased parts, which showed that process of nature in closing the artery completed, which in the former case had only been begun, although a longer period of time had elapsed.

We were inclined to suppose that the aneurismal sac existed prior to and independent of the gun-shot wound, considering that a sac of that nature could not be formed in ten days. Captain St. Pol did not remember any injury to have happened to, or any painful sensation to have existed in the knee before the accident; but Dr. Armstrong recollected his having once or twice mentioned some uneasiness in it, but in so casual a manner as not to have caused further inquiry. The other end of the artery I could not find from the gangrenous state of the parts. He was a remarkably handsome young man, and died beloved and regretted by every one.

Private P. Turnbull, of the grenadiers of the 74th regiment, of good stature, was wounded on the 10th of April, 1814, at Toulouse, by a musket ball passing from the inside to the outside of the middle of the thigh; he says it bled considerably at first, but soon ceased; the wound was not painful, and he thinks he observed the leg and foot to be colder than the rest of his body for the first two or three days, but did not much attend to it, further than conceiving the numbness, coldness, and impeded power of motion as natural to the wound.

On the 18th of April the gentleman in charge of this patient pointed him out to me as an extraordinary case of gangrene coming on without any, as he supposed sufficient cause; the wound on the outside of the thigh, or the exit of the ball, was nearly healed, and that on the inside was without inflammation or tumefaction, and with merely a little hardness to be felt on pressure. The pulsation of the artery could be distinctly felt to the edge of the wound, but not below it; the leg was warm, the gangrene confined to the toes. The artery of the other thigh could be distinctly traced down to the tendon of the triceps. As he was at a small hospital, about two miles from town, on the field of battle, I did not see him until the 20th, and again on the 23rd, when, although the gangrenous portion included all the toes, it had the appearance of having ceased. Satisfied that it would again extend, I left directions with the assistant-surgeon that the limb should be amputated below the knee.

The surgeon, who I had not seen, and who did not understand the subject, disobeyed the order, conceiving that there must be some mistake. At daylight on the 25th I was greatly annoyed on finding that the operation had not been done, and that the mortification had begun to spread the evening before. It was then too late. On the 26th it was above the ankle, with considerable swelling up to the knee. At night the man died; and the next morning at six o'clock I removed the femoral artery from Poupart's ligament to its passage through the triceps, which part was affected by the mortification.

The ball passed between the artery and vein in the spot where the vein is nearly situated behind it, and adherent only by cellular membrane, through which the ball made its passage, the coats of the vein being little injured, and those of the artery not destroyed in substance, although bruised; it was at this spot much contracted in size, and filled above and below by coagula, which prevented the transmission of blood, and the vein above and below the wound was filled by a coagulum, and was also impassable. This preparation is unique, and is perhaps the only one in existence proving the elasticity which vessels possess, and their capability of avoiding to a certain extent an injury about to be inflicted upon them. It will be hereafter in the museum of the Royal College of Surgeons, for public inspection.

CASE 24.—After the battle of Salamanca, I was requested to see a soldier of the fifth division, who had received a shot in the thigh nearly in a similar place, which had been followed by gangrene of the toes, not extending to the instep. The correctness of my opinions not being at that time acknowledged by my friend the surgeon, who showed the case to me from knowing my desire on the subject, he did not amputate when the mortification began to spread suddenly, and this man also died on the day after that occurrence.

CASE 25.—A Portuguese, at the same battle, suffered from a wound of a similar nature, but rather lower in the thigh. The mortification which followed was confined however to the great toe only, and great hopes were entertained that it would not spread, when hemorrhage unexpectedly took place from the wound, and the artery was tied some distance above it. The hemorrhage returned and was suppressed, but the patient sunk and died. On examination it was found that an additional, but this time an accidental error had been committed (I have seen it since done in London), and that a large branch from the femoral artery running parallel with it had been tied instead of the wounded artery itself, which had yielded by ulceration, not having been cut in the first instance.

CASE 26.—Don Bernardino Garcia Alvares, captain of the regiment of Laredo, thirty years of age, was wounded at the battle of Toulouse by a musket ball, which passed through the thigh, a little above its middle. The wound was not considered a dangerous one until the 30th, twenty days after the injury, when a considerable bleeding took place; and as the vessel from which it came seemed to be very deeply seated, the Spanish surgeon in charge tied the common femoral artery. I saw the gentleman in consequence of this having been done. The hemorrhage was suppressed by the operation, and the limb soon recovered its natural temperature, but gangrene made its appearance on the great toe on the third day afterwards. It did not seem to increase, but the limb swelled as if nature was endeavouring to set up sufficient action to maintain its life, and this continued until the tenth day after the operation, when he died completely exhausted. On the dissection of the limb, the femoral artery was found to be perfectly sound in every part below where the ligature had been applied. The vessel which bled could not be discovered; but it was certainly a branch from the profunda, and not the femoral itself. In this case the ligature of the femoral artery destroyed the patient, and the practice pursued must be condemned. The gunshot wound should have been largely dilated, at both orifices, if necessary, until the wounded vessel was discovered, which was in all probability not completely divided by the ulcerative or sloughing process which had taken place, and the division of it would in all probability have suppressed the bleeding. I shall refer to this case hereafter.

Cases of wounded arteries were not numerous after the battle of Waterloo, as far at least as they were observed in the hospitals in Brussels and at Antwerp.

CASE 27.—In one which occurred in a French prisoner in the Gend'armerie Hospital, and for which the femoral artery was tied, it proved fatal from gangrene of the foot and leg.

Three cases have occurred at the Westminster Hospital under my observation, in which mortification of the leg took place from injury to the popliteal artery. The two first were not under my care, and were both in my opinion lost, in consequence of the early signs of loss of life not being recognised until too late. They both died waiting for the mortification to stop by the establishment of a line of separation between the dead and the living parts, which under similar circumstances rarely takes place. In both these cases the amputation should have been done immediately above the knee, including and removing all the injured parts, and before inflammation had set in to any extent.

CASE 28.—A lady suffered from mortification of her right leg, without any obvious cause, and desired my attendance. The mortification resembled so much that which follows a divided artery, that I immediately examined the thigh, and found the femoral artery up to Poupart's ligament had become a hardened cord, without pulsation. She had suffered an attack of inflammation in it. A line of separation having been formed behind the knee, I amputated the thigh immediately above it. The lady died some days afterwards; and the limb and the artery are in the museum of the College of Surgeons.

The result of amputations, after a line of separation had been formed, during the Peninsular war was not favourable, it was in fact so much the reverse, when the constitution of the sufferer was impaired by disease or was otherwise unsound, that I was led to abandon it in many instances, and to adopt a different proceeding in the following case, which deserves consideration, inasmuch as I have little doubt that death would shortly have followed after an amputation.

CASE 29.—Richard Cook, aged fifty, a mason, whilst sitting on a square block of stone, on the 23rd February, was struck by another, which drove the popliteal space or ham against the edge of the block on which he sat, giving him great pain, and otherwise greatly bruising the leg, although no bones were fractured, nor was the skin torn. The limb on his admission, half an hour afterwards, into the Westminster Hospital, was much larger than the other, and of a dark reddish-blue colour, evidently from the bruise or extravasation of blood, which appeared to be still issuing from the vessel or vessels, as the limb continued to increase in size until it became at last greatly swollen. The pulsations of neither the anterior nor the posterior tibial artery could be distinguished through the swelling the next morning. The bowels were opened, and a cold spirit lotion was applied to the calf, and around the leg, and the swelling somewhat subsided, the limb becoming quite a blue black, which, with the tenseness of the parts, distinctly indicated the effusion of a large quantity of blood. It was soon obvious that greater mischief had occurred than had been expected, and on the 2nd of March, as vesications filled with a bloody fluid were formed on the outside of the leg over the fibula, and the whole limb was manifestly about to pass into a state of gangrene, if it had not already done so, I prepared everything for tying the popliteal or other arteries, if found necessary, and made a long and deep incision on the outer and back part of the leg, through the integuments and muscles, posterior to the fibula, and removed a considerable quantity of coagulated blood from between the muscles and from a large cavity which extended upwards into

the ham, without causing further hemorrhage, and in no part of which cavity could an artery be felt. The patient's countenance and body had assumed a jaundiced hue; the pulse was very quick, the tongue foul, the countenance sunken, the skin hot, the head wandering. Poultices of linseed meal and stale beer were applied, with gentle stimulating applications. Brandy and wine were ordered in proper quantity every hour or two, with sufficient doses of the muriate of morphia at night to allay irritation, and to induce sleep. The incision, together with these remedies, gave great relief, and on the 7th the man seemed to have been saved from a state of the most imminent danger. On the 8th the pulse was 112, the tongue clean, the skin of a whiter colour, the bowels opened by injections; eight ounces of brandy were given in the twenty-four hours; wine, with sago, arrow-root, jelly, oranges, and anything he chose to ask for. The greatest cleanliness was observed, and the chloride of lime was used in profusion all around him. The mortification of the limb was complete, a line of separation formed about four inches below the knee in front, and extended behind towards the ham. On the 26th, the dead parts having almost entirely separated from the bones all round, those which remained were cut through where dead, and the bones were sawn through about five inches below the knee, and the lower part of the limb removed, leaving an irregular and in part granulating stump, with an inch of bone projecting from it. On the 24th of May this portion was found to be loose, diluted nitric acid had been applied to its surface, and on the 20th of June it separated. On the 16th of August Cook left the hospital in good health, with a very good stump, having cost the hospital £57 in extra diet.

In this case, there can be little doubt of the popliteal artery having been torn, and if the incision made on the 2nd had been had recourse to during the first two or three days, and the artery sought for, and secured if found bleeding, it is possible the mortification might have been prevented, although it is probable, from the pressure arising from the great extravasation and coagulation of blood, that the collateral circulation was so much impeded as not to have been able to maintain the life of the limb below, even during that time. The incision made on the 7th saved the life of the patient by taking off the tension of the part, and relieving thereby in a remarkable manner the constitutional irritation which hourly appeared likely to destroy him; indeed, no one expected anything but his dissolution. When the line of separation had formed, he was evidently unequal to undergo the operation of amputation, to make a good stump without great risk, and the dead parts were therefore merely separated for the sake of cleanliness and comfort. Experience had demonstrated in too many cases of the kind that the formal operation of amputation at this time as recommended by most modern surgeons would in all probability have cost him his life.

CASE 30.—In 1834 I placed a ligature of strong dentist's silk on the right common iliac artery of a lady of middle age for a swelling in the hip, supposed to be a gluteal aneurism, and which, after commencing the operation, was found to occupy a considerable part of the iliac region. The lady died a year afterwards, and it was then found that the ligature had been applied at the distance of five-eighths of an inch from the bifurcation of the aorta, and three-eighths of an inch above the origin of the internal iliac, independently of the line of separation between the parts of the iliac divided by the ligature, and which does not seem to be wider than the ligature itself. The separated ends were united at the point of separation by new matter, the orifice or end of each being closed by a very narrow barrier, the inner coat of the artery being redder than natural, somewhat irregular and contracted, and containing hardly any coagulum, thus proving the fact, in the largest artery in the body save one, that a coagulum is not necessary for the safety of the union; while the immediate vicinity of so large a vessel as the internal iliac, to say nothing of the [illegible] itself, also proves that the danger hitherto [illegible]ed from the neighbourhood of a collateral is more imaginary than real—two great [illegible] the practice of the Peninsular war led me to declare, and which can no longer be doubted.

The preparation exemplifying these points is in the Museum of the Royal College of Surgeons, together with the ligature, still carrying in its noose the portion of the artery it strangulated and brought away with it.

The mortification of the extremity, which, from what I have said, might reasonably have been expected to take place from a defective or unestablished collateral circulation, was, I apprehend, prevented by keeping up a regular gentle friction, by the hands of a nurse, on the foot and leg up to the knee, for the first twenty-four hours almost without intermission, and at short intervals afterwards, until the re-establishment of the circulation could not be doubted. I had previously tried it in a case of inguinal aneurism, for which I had placed a ligature on the external iliac artery, less than an inch from its origin from the common iliac, by a similar operation, not knowing which vessel I should have to tie, from the extension of the tumour upwards, in which case it succeeded equally well; and I am not without hope that if this practice should be duly followed up in all cases of wounded arteries of the lower extremity, and in some of the upper, that the danger from mortification may be greatly obviated.

Some practical deductions may be made from these facts.

1. That the theory of the operation of aneurism, as dependent on the collateral circulation, cannot be applied with safety to spurious aneurisms of recent occurrence dependent on wounded arteries.

2. That it is inapplicable to wounded and bleeding arteries.

3. That the length of time a spontaneous aneurism has existed is of consequence, as connected with the collateral circulation; although an aneurism should never be allowed to attain that size which may render it injurious to the surrounding parts.

4. The collateral vessels are at all times and, under all natural circumstances capable of carrying on the circulation in the upper extremity, whatever disease or injury may affect the principal trunk, provided a due degree of care be taken to maintain the temperature of the part. Whenever the reverse takes place, it is an exception to the general rule.

5. After operations for aneurisms in the lower extremity, the collateral branches are almost always equal to carry on the circulation through the limb.

6. When the principal artery of the lower extremity is suddenly divided, without any previous disease having existed, mortification is not an uncommon occurrence, and is more likely to take place in old than in young persons.

7. When under such circumstances the principal vein is also divided, mortification seldom fails to be the consequence.

A Course of Lectures on Hernia,

BY JOHN FLINT SOUTH, Esq.,

Surgeon to St. Thomas' Hospital, and Professor of Surgery to the Royal College of Surgeons.

(Delivered in the Theatre of the College, and revised by the Professor for the MEDICAL TIMES.)

LECTURE II., continued.

Chronic and inflammatory strangulation—spasmodic strangulation—Remarks on coughing, as affecting strangulated ruptures—Mr. Luke's opinions—Bulk of a rupture, as affecting the symptoms of strangulation—Strangulation in irreducible ruptures, without increase of the bowel protruded. More common causes of strangulation: possibility of distinguishing the contents of the sac. Mr. Pott's case. Elasticity. Doughy feel. Necessity of careful inquiry into all cases of peritonitis and enteritis. Treatment of strangulated rupture; Taxis; Precautions; Necessary aids to its use; Mode of application; Effects of large quantities of fluid in the sac; Effects of a band in lower part of the sac; Hot bath; Bleeding; Blood should be drawn rapidly. Remarks on the effects of violence in the use of the taxis; Petit's opinions; Bodily reduction. Cases of Le Dran, De la Faye, Arnaud, Scarpa, Sabatier, Sanson, Dupuytren, Sir Charles Bell. Case by Green and Callaway; Case by Bransby Cooper; Neglect of this subject by English surgeons; Mr. Luke's paper in the Royal Medical and Chirurgical Transactions.

The symptoms of strangulation may be comparatively slight, or they may be severe; they may creep on slowly and insidiously, or they may come on quickly. Hence they have been described by some surgical writers as being indicative of chronic or of inflammatory strangulation. The condition of the strangulated bowel does not, however, sustain these designations; for very commonly, severe symptoms set in immediately on strangulation taking place, and depend rather on the tightness with which the bowel is girt than on inflammatory action, which is a consequence rather than a condition of strangulation; a circumstance arising out of the unnatural state of the gut and not that which causes it, and the first step on the part of the constitution to provide against the mischief which will of necessity ensue, should the strangulation be left unrelieved. A spasmodic strangulation is also occasionally spoken of, but improperly, for except in ventral and phrenic ruptures, in which the protrusion is through the muscular fibres, the muscles do not exert any material influence on the apertures by which the bowels escape, and consequently have nothing to do with the matter.

There is a symptom ascribed to strangulated ruptures by some surgeons which it might be supposed I had overlooked; but I have purposely omitted mentioning it till now, because as I believe it neither can nor does exist, I think it has been improperly included—I mean dilatation of a strangulated rupture on coughing or sneezing. If the strangulation be sufficiently tight to prevent the return of the bowel into the belly, in the ordinary methods of attempting its reduction, it will also be sufficiently tight to prevent the protrusion of more bowel through the mouth of the sac, which is choked by that already escaped; and the tightness with which the gut is girt is, as almost every surgeon must have observed who has had ordinary experience in the treatment of this disease, so complete, that in operating on a strangulated rupture, after the sac has been opened and the gut exposed so that it can be compressed with the greatest effect, yet it cannot generally be emptied of its contents, either fluid or air, nor is more gut forced down, nor the bulk of that already escaped increased by the patient's cries, nor by his holding his breath that he may better bear his pains. There is no alteration in the bulk of the protruded bowel, nor is any more forced out; and this, therefore, must be considered to prove that a strangulated rupture cannot dilate. I readily admit that in strangulation, when the patient is directed to cough there is often an impulse, a forcing of the rupture-swelling against the hand which grasps it, but this is not dilatation, and arises from a totally different cause, which will be best understood if, by anticipation, I refer to scrotal rupture. The part of the sac in which the rupture is strangulated is sometimes at the external, sometimes at the internal abdominal ring. If the former, when the patient coughs, he forces more bowel into the inguinal canal, which drives against the stricture and strictured part, and thrusting down bodily the sac and its contents, pushes it against the hand and thus produces an impulse, but without increasing the actual size of the rupture below the stricture by forcing anything into it, consequently *it does not dilate*. Again, if the stricture be at the internal ring, the effort of coughing forces the bowels in the belly against it and the bowel which it tightly girts, and driving the sac with its contents below, forces it against the hand, and produces an impulse, but still without dilating or increasing the bulk of the contents of the sac below the stricture.

Now, although this is undoubtedly the general rule, yet there is an exception which actually supports it. When the strangulation is not in or near the mouth of the sac, but when it is caused by a fibrous band crossing from one to the other side of the sac, then, when the patient coughs, more bowel is forced through the mouth of the sac, and the rupture-sac is dilated by the additional quantity of bowel for the time thrust out, and which, is very different from the impulse felt under the former circumstances.

In this way, I think, may be fairly and truly explained that which is commonly called dilatation of

a strangulated rupture during coughing, which is no actual enlargement of the rupture, swelling itself, but simply an alteration of its position by the driving of the bowel above against the stricture at whatever part situate, provided such stricture be not formed by a fibrous band or omentum, in the body of the sac.

For the first notice of this fact, so far as I am aware, we are indebted to Mr. Luke, who does not, however, direct it to the explanation which I have given, but simply to the determination of the seat of stricture in a rupture. He says, "If the body of a hernial tumour be compressed by the hand, an impulse is given to all its parts below the seat of stricture; but if the neck of the hernia be grasped between the finger and thumb of the other hand above the stricture, while such compression is made, there will not be any impulse felt." It is true, indeed, that he does not oppose the terms impulse and dilatation, but it is equally true that the two expressions convey decidedly different meanings, and designate different kinds of action in the rupture.

The symptoms of strangulation are not violent in proportion to the great bulk of a rupture, but rather the contrary, as they are usually more severe when the rupture is of small size. The easy explanation of this is afforded by bearing in mind that the symptoms are proportioned to the tightness with which the protruded bowel is girt by the stricture, which must necessarily be less when the rupture has a large mouth, and permits a large protrusion of bowel that cannot be so completely and immediately constringed, as when the aperture of the sac is small, and the protruded bowel of small quantity. In addition to which it may be observed that the mouth of an old rupture-sac is more accustomed to the pressure of the long protruded bowel, than a small and newly-formed rupture, the mouth of which violently opposes the protrusion, and consequently more tightly girts the bowel which has passed through it.

Strangulation may follow an irreducible rupture, without any increase of the protrusion, but simply by the lodgment of fæces in the protruded bowel, or even by the collection of air within, so that it becomes distended, and cuts off the communication between the bowel above and that below the rupture. Or its distension may so interfere with the vessels of the bowel, that the blood being unable to return by the veins, its serous part is poured out into the cellular tissue of the bowel, so that the thickness of its walls is greatly increased, and thus by its greater bulk, it actually strangulates itself completely, if it had not done so before.

More commonly, however, strangulation results from the sudden escape, on exertion, of more bowel than usually passes through the mouth of the rupture-sac, which will yield, to a certain extent, to the force exerted against it; but when the force is withdrawn, the mouth of the sac recovers its ordinary size, grips the protruded bowel so tightly as to prevent it moving one way or other, and thus causes strangulation. Here again, also, when the bowel has become constricted, the return of the blood is less or more prevented, according to the tightness with which the gut is girt, and serum is poured into its cellular tissue, so that it becomes of larger bulk than natural, and by so much less capable of being returned and renders its strangulation still more tight.

It is frequently said that the contents of a rupture-sac can be distinguished from each other; this, however, I very much doubt, and more especially as it often happens that both intestine and omentum form the contents of the sac.

It is said that the symptoms of strangulation are less severe in omental than in intestinal strangulation; but Mr. Pott's case, to which I have already alluded, shows that the descent of omentum alone, even without strangulation, will produce vomiting —one of the most important signs of that condition —whilst, on the contrary, gut is often found strangulated, when there has been little or no vomiting. The elastic feel is also often mentioned as a symptom of intestinal protrusion, and a doughy feel as that of omentum. These, however, are very uncertain characters, as, when a rupture has been coarsely handled, a not unfrequent occurrence, serum may be poured into it, or even blood extravasated, and the doughy feel produced, though the sac contain only gut, whilst, on the contrary, there may be much fluid in the sac, together with omentum, and little or no intestine, and thus the swelling be elastic. Practical experience, therefore, shows that attempts to distinguish between the contents of the sac are uncertain and unsatisfactory, and it may be added useless, as the requisite treatment is the same under both conditions.

As the symptoms of inflamed peritoneum, or of inflamed bowel, or both together, when arising from other causes, are similar to those observed immediately or very soon after strangulation has taken place, and as the former requires only medical treatment, whilst the latter continues increasing till relieved by the surgeon; it is always of the utmost importance that when such symptoms set in, careful inquiry should be made as to the existence of any swelling upon or in the neighbourhood of the belly, which can possibly be a rupture and the cause of such symptoms. And if there be doubt of the truthfulness of the patient's answers, or suspicion that the questions put be not understood, an examination must be made, so that the medical attendant's mind should be freed from doubt. This more specially applies to women, who though aware of the existence of such tumours, either through ignorance or false notions of modesty, conceal them, and consequently die from want of surgical relief; it must not, however, be forgotten that there may exist at the same time peritoneal inflammation, and swellings on or in the neighbourhood of the belly, and yet neither connected with the other, as such swellings are not always produced by ruptures. The tumours which may be confounded with ruptures, will be more conveniently noticed when treatment of particular ruptures with which one kind or another of swellings has resemblance. At present it is only necessary to direct attention to the fact.

Treatment.—When a rupture is strangulated, and the symptoms already described have appeared, the object of the surgeon should be to return its contents as speedily, cautiously, and perfectly as possible. This is done in the less close constriction of the bowel by a peculiar kind of handling, to which the term taxis is applied, either alone or aided by constitutional treatment; or, if the confinement of the bowel be so complete that these are unavailing, then recourse must be speedily had to a surgical operation by which the constriction is removed, and the contents of the rupture returned into the belly, after which, under favourable circumstances, the symptoms subside, and the patient recovers.

Use of the Taxis, &c.—Previously to attempting reduction by the taxis it is advisable to place the patient in such a posture as will completely relax the abdominal muscles, and prevent them offering any great resistance, in the patient's straining, to the efforts making for the return of the bowel. The relaxation of the muscles has also in some cases a beneficial effect on the mouth of the rupture-sac itself, by freeing it from such further confinement as they to a certain extent are capable of exerting on it. The patient should therefore be laid on a sofa or bed, upon his back, with his shoulders and nates well raised, whilst the back and loins are sunk at the same time; the knees are to be bent up towards the belly, close together, and the soles of the feet resting on the bed. The surgeon then, with his right hand, grasps if possible, the whole swelling, having its base in the hollow of his palm, and the fingers and thumb spread lengthways over it, and their tips directed towards the neck of the rupture. With the fingers and thumb of the left hand he grasps the swelling at the neck, and at a right angle to the other hand. The hands being thus placed, with the right he makes gentle pressure over the whole swelling, by which the fluid, more or less in quantity, usually there existing, gradually flows back into the belly, and then presses the solid contents of the sac up towards its mouth. Whilst this is doing, the fingers and thumb of the other hand are alternately moving, to thrust up by little and little, or as it were to knead, small portions of the protruded bowel into the mouth of the sac. If these efforts be successful, a movement is felt in the contents of the sac, and if gut have been protruded, not unfrequently a slight gurgling is sometimes felt, and at other times even heard, which is a favourable sign, as showing that the contents of the protruded bowel are passing into that within the belly, and commonly, soon after this occurs, the bowel itself moves more rapidly, and often at last escapes from the sac with a rush. At other times no gurgling is perceived, but the bowel is felt slowly moving from the fingers, till the sac has become completely empty.

Occasionally it happens that the quantity of fluid in the cavity of the sac is so large, and that of bowel so small, that comparatively little effort diminishes the size of the rupture so considerably that the reduction is thought to have been perfected, and the surgeon is satisfied, and leaves off the handling. But to his disappointment he finds, in a short time, the swelling as large as ever. He presumes the rupture has again descended by the patient's improper exertion during his absence, and repeats the taxis with similar effect; the swelling, he believes, has been got rid of, but after a time it reappears, and he then becomes puzzled with the case, as he feels convinced he has again and again returned the contents of the sac. Such a case is by no means unfrequent, and is an annoyance to inexperienced or thoughtless persons; but the difficulty is easily explained: the surgeon has merely emptied the fluid from the sac, and has left the bowel unreduced. Considerable diminution in the size of the rupture may also take place by the use of the taxis, when the strangulation is caused by a band in the lower part of the sac. This, of course, depends upon the gut above the stricture being emptied of its contents, whilst the strangulated portion remains undiminished in size, and unchanged in place. Therefore, when this happens, it must be recollected that the patient's danger is unrelieved, and that the operation will be required.

When the reduction is effected, the finger can be pushed almost invariably up through the mouth of the sac into the belly; and until this can be done, it cannot be determined that the bowel is returned. The practitioner, therefore, should not give up till he finds he can do this, and if he cannot, he may presume that an operation is necessary for the patient's relief, and should be resorted to without delay.

It is the ordinary practice to attempt reduction in the way described, before resorting to any constitutional treatment, by which it may be rendered more easy; but if this do not soon succeed, it is better at once to depress the patient's powers by putting him into a hot bath, if it can be readily obtained; and bleeding him quickly till he be ready to faint, or actually does faint. But if the bath cannot be procured, then bleeding should be resorted to. It would seem scarcely worth while to observe that the blood should be taken quickly, and by a large orifice, were it not that this is too frequently unattended to. But this is a point of much importance; it is not the *quantity* of the blood taken, but the *quickness* with which it is drawn, that produces the desired sudden effect upon the constitution. Twice as much taken from a small opening and slowly, will not have the effect which less than half has, when drawn from a large wound and quickly. The patient then having been kept in the bath for a sufficient time to make him feel faintish, should be directed to stand up, a vein in one or both arms freely opened, and the blood allowed to flow till he begin to totter, and then just as he is on the point of dropping, he should be quickly laid down, and the taxis immediately employed, as he is then, in consequence of the great prostration of his strength, in the most favourable condition for effecting reduction, which frequently is managed under such circumstances. If, however, the strangulation cannot be overcome, the operation must be resorted to; but it is always advisable after the patient has been removed from the bath, and either temporarily put to bed whilst the necessary preparations are made, or even when he is placed on the table, to make one last effort at reduction, as I have more than once or twice known this final attempt successful, which may be presumed to have depended on some small portion of the protruded bowel having been drawn from within the stricture by the swaying of the bowels within the belly one way or another in the mere act of lifting the patient about; and, as I have already mentioned,

it commonly happens that when a small portion of the constricted bowel has moved, or been moved from within the stricture into the belly, the rest may usually be made to follow.

In employing the taxis care must be taken that violent pressure should not be made; and also that even moderate pressure should not be too long persisted in, as from both these causes the patient's danger is considerably increased; and to them may be ascribed the unfavourable condition in which patients are too frequently, when brought to the hospital, in addition to the too long delay of the operation. The most common result of this improper treatment is that the swelling is rendered so exceedingly tender, that it will not bear the most gentle handling without great pain. When this is the case, it is always best to bleed the patient before making any further attempt with the taxis, and when this is employed, it must be with great caution, or the surgeon will complete the bad treatment already commenced, by bursting the gut, if gut be down. If, therefore, there be much tenderness, and more especially if the skin be inflamed, and the cellular tissue loaded with serum, or it may be with extravasated blood consequent on the violent efforts already made, it is better after having gently ascertained the fixedness of the rupture, at once to proceed to operate, and not unfrequently when the sac has been laid open, the bruised state of the bowel, and the bloody serum in which it is bathed will certify the propriety of the proceeding.

Petit warns against violence in the use of the taxis, and still more to its repetition:—"It is always dangerous," says he, "and still more so when there is any hard, pointed foreign substance in the intestine, as in the case of a cook, who had swallowed a lark's leg; he had been so worn out for three days by the rough and repeated compression to which he had been subjected by a truss-maker, that it might be readily imagined such handling would not only cause gangrene, but tear and pierce the gut. I have seen," he continues, "a woman, sixty years old, in the same condition from a large pin; which I found after having opened the sac; part of it was in the gut, and part in the sac with a considerable quantity of stercoraceous matter. In other instances I have found worms, cherry and plum-stones, raisin-stones, and the small bones of sheeps'-feet: in the latter case fifteen days had passed since the bones had been swallowed, in eating a fricassee of feet." In the College Museum is an example of the protruded gut being choked up with apple or potato peel.

These foreign substances can sometimes be emptied from the gut, of which Petit mentions a case in which he "found cherry-stones in such quantity that they completely filled the whole of the gut in the rupture; he fortunately succeeded in passing them into the part within the belly, and reduced the rupture."

When the gut is burst by violence, the swelling either entirely or in part almost immediately subsides, the contents of the bowel quickly finding their way into the cavity of the belly, and the patient dies, sometimes without and sometimes with symptoms of peritoneal inflammation; but the burst intestine commonly remains in the sac.

Another and equally dangerous result, if undiscovered, of violent application of the taxis, is the reduction of the peritoneal sac and its contents still contained within it, into the cavity of the belly, either before or behind the peritoneum, as may chance. This is called by the French surgeons, "reduction en masse," or "reduction en bloc," and which we call after them "reduction in mass," but which would perhaps be better designated by the workman's phrase "bodily," and we should then call it a "bodily reduction of the rupture." Fortunately for us such occurrences are but rare in this country, and very few museums present examples of such unwarrantable violence.

[illegible]e accident was first noticed and described by Le Dran, in a case of femoral rupture, which had been reduced twenty-four hours after strangulation The symptoms continued, and at a week's end Le Dran was called to visit the patient, but it was too late to attempt any operation, and on the following day he died The [illegible]geon first in attendance stated that at the time of the reduction he did not hear [illegible] noise the intestine generally makes when it enters the belly; and that the parts composing the rupture passed in a heap under the ligament like a tennis-ball." Upon opening the body "the hernial sac was found in the belly (at what part is not stated), about three inches in depth and eight in circumference, and within it was contained half an ell of the jejunum." Other cases are mentioned by De la Faye, Arnaud, and Scarpa; more recently Sabatier, Sanson, and Dupuytren have also met with them, and the latter no less than six. Sir Charles Bell mentions a case of this kind.

The museum of this college possesses a preparation of an inguinal rupture which had been reduced in mass between the abdominal and iliac muscles and the peritoneum; part lies below the crural arch, and extends outwards nearly as far as the crural vessels. It forms a large swelling inwards towards the cavity of the belly, but is not visible externally. The rupture had been of long duration, and the patient had never worn a truss, but he was not inconvenienced by it, nor had ever any difficulty in returning it till it became strangulated.

Another case occurred to my friends Green and Callaway. The patient several years before had, whilst in Spain, symptoms of strangulation, and a swelling in the scrotum, which having been pushed up by a Spanish surgeon, after a time the symptoms subsided, and he had no further inconvenience till 1836, when he had a swelling in the left (the same) side of the scrotum, accompanied with symptoms of strangulation. It was transparent and irreducible. No relief having been obtained by medicine, it was determined to perform an exploratory operation. A cut was, therefore, made into the swelling, which evacuated the fluid, and the finger being introduced, moved freely about, and the intestines were felt, as it seemed, in the general cavity of the belly, and free from strangulation. The symptoms, however, continued, and he died a few days after. On examination it was found that the finger did not pass from the cavity opened in the scrotum into the general cavity of the peritoneum, but into a large sac lying between the iliac fascia and iliacus muscle, and containing the intestines which were strangulated in a small aperture at the upper and inner side of the sac, where was the communication with the cavity of the belly The testicle lay behind the scrotal sac just at the external ring. Mr. Green presumes that the rupture was originally congenital, that the whole rupture and testicle had been violently thrust up into the belly by the Spanish surgeon, the sac doubling on itself; but that the intestine had then partially or completely relieved itself; that the sac had subsequently lengthened downwards, forming the tumour filled with fluid, which was contained in the scrotum, and had been cut into.

Mr. Bransby Cooper has also mentioned, in Guy's Hospital Reports, a case of reduction in mass, under his care in 1839, in which there were two sacs.

FIBROUS TUMOUR.

(Continued from page 41)

Mrs. W., aged thirty-five, tall, emaciated, haggard September 27, 1845.—Much pain of abdomen extending over the whole of the lower half, close down to the symphisis pubis and to the sides, increased to intense suffering by pressure and moving about, especially in a carriage; constant sensation of throbbing in the abdomen and of internal movements, like those of a fœtus, with a feeling of weight and pressure in and about the pelvis, occasionally amounting to acute pain; much gastric irritability bowels in a very unhealthy condition; leucorrhœa great debility and occasional faintings.

Married Nov., 1843—became pregnant January, 1844. Had severe morning sickness and other sympathetic derangements, which lasted until October. She had a slight show of the catamenia at the end of the first month, and a slight trace at the end of the second; in other respects she enjoyed good health during pregnancy. In October she was delivered, after a severe labour of thirty-six hours' duration, of a full-grown fœtus, which appears to have died ten days before birth. She recovered quickly, and continued remarkably well until February, 1845, when she was exposed to considerable mental excitement and alarm, supposing herself at the time to be some weeks advanced in her second pregnancy, having missed once or twice. A slight show of the catamenia appeared in March. In April she had rather a severe fall, and in two days afterwards was seized with a violent flooding, by which she was much reduced. In seven weeks after this event she again missed a catamenial period, and shortly afterwards had what was supposed to be a miscarriage, but she did not decrease in size. In the course of a week or two she began to have a sensation of movements in the abdomen, like those of a fœtus, which have continued ever since. In seven weeks after the supposed miscarriage she had another flooding, during all which period she had many pains and other sensations which she had never experienced except when pregnant, but she was unable to lie in any posture except upon the left side with one knee bent strongly on the body. From about the time that she first felt the fœtal movements she began to have violent pulsation in the abdomen, particularly about the umbilicus.

In August her medical man, and also a married female friend, considered that they had distinctly felt the movements of the child in the lower part of the abdomen on the left side, but not at all on the right side. Since then she has continually had a painful sensation of weight in the pelvis, which at times is very acute, and a constant feeling of a foreign body situated just above the symphisis pubis, increased on moving or by any shock.

Very early in the present month, whilst lying on the sofa, she was suddenly seized with violent pain in the back and loins, more like labour-pains than anything else, except that the pain was constant, without intermission. She had severe vomiting, which lasted for four days; on the second she threw up a large quantity of green bile. Since the second attack of hemorrhage the size of the abdomen has gradually diminished, and since the above mentioned bilious attack, during which she took some active doses of calomel, she has diminished still considerably, so that now she is not much above her ordinary size. About a fortnight ago the discharge again returned and lasted four days; it was without coagula, and resembled the catamenia.

Examination of Abdomen.—A deep-seated hardness, intensely tender when reached by the pressure of the finger through the abdominal parietes, is to be felt extending from behind the symphisis pubis (where it seems in contact with the posterior part of the fundus uteri which it pushes forwards) up to or above the umbilicus, extending two or three inches to the left of the median line, and to a much greater distance on the right side. The edge appears well-defined wherever I can feel it

Examination per Vaginam and Rectum.—The uterus, as far as can be reached per vaginam, is small, but normal; the os and cervix, small, but soft and not tender; the uterine sound passes easily upwards and forwards to the natural extent; pressure with the hand close behind the symphisis pubis, and somewhat to the right, moves the uterus very distinctly.

I merely prescribed a slight laxative, and on September 29th requested my friend, Professor Simpson, of Edinburgh, who happened to be then in town, to meet me in consultation. On passing the sound, he succeeded in introducing it further than I had done, viz., beyond a sort of prominence, which I had supposed was the fundus; it then ascended to a considerable distance above the symphisis pubis, so that the movement of its point could be distinctly felt through the anterior wall of the abdomen. He, therefore, came to the conclusion, that this elongation of the uterine cavity was owing to the presence of a fibrous tumour occupying the posterior wall of the uterus, portions of which could be felt through the abdominal parietes, and, from the pain produced by external and internal examination, that it was in an actively

inflammatory condition. He advised leeches to be applied per vaginam; a slight mercurial course, and the application of mercurial ointment to the os and cervix uteri.

October 14.—Since last report eight leeches have been twice applied to the upper part of the vagina, behind the cervix uteri; they bled very freely each time, with manifest diminution in the tenderness of the mass; it is difficult to say whether any alteration in size is perceptible. She has taken pil. hydrarg. gr. v every night for ten nights, when the mouth became slightly affected; but in four days afterwards she caught a slight cold, and suffered extremely from salivation, sore mouth, and pain of face, which was relieved by fomenting with hot decoction of poppy. Bowels have been kept open by the following pill:—

R. Extr. aloes aquosi, ℈ij; Extr. hyosc., ℈iss; Mastiches, gr. xij. M. ft. pil., xx; Sumat ij, h. s.

24.—Mouth nearly well; feels much better; has had no attack of severe pain for the last five days. Throbbing continues at times, but in less degree. Since the last leeching there has been much pain across the lower part of back, with a brownish watery discharge, sometimes very dark, thick, and fetid; much headache; bowels more open since she has returned to her usual diet; spirits are better. The size of abdomen varies at times considerably, but she thinks that occasionally it returns quite to the natural size; it is decidedly much smaller since coming to London. Pt. pil.

30.—Leeches were applied on the 28th, in consequence of increased pain, throbbing, and tenderness of abdomen after going out in the carriage. The leeches bled well and with relief.

November 11.—Cervix uteri *distinctly* longer. I fancy that the tumour is less on the left side; there is *much* less pain at this spot, nor does it seem to extend so high up.

Having directed the speculum carefully *behind* the cervix uteri, it passed to its fullest extent; eight leeches were applied to this part, and apparently with better effect than ever.

27.—Leeches were again applied on the 21st, but did not take so well this time. A considerable discharge, like catamenia, came on yesterday, but it does not seem to have weakened her much. The tumour is certainly less painful. As the bowels are not sufficiently open, I ordered

R. Pil. hydrarg., Extr. coloc. co., ãã gr. v, hâc nocte sumenda.

R. Acid. hydrochlor. dil.; Acid. nitrici dil., ãã m. viij; Syrupi aurant., ʒj. Infusi gentianæ co., Infus. sennæ co., ãã ℥v. M. ft. haust. bis die sumend.

I continued to apply leeches at intervals of about a fortnight, until February, regulating the bowels with an occasional brisk purge, or by the above-mentioned draught. Not only had the general health improved considerably, and she had gained flesh, but the tumour could not be felt so distinctly through the abdominal parietes, and pressure during the examination produced but little pain.

On the 13th of February I began to apply the unguentum hydrargyri fortius, rendered harder with a little ceratum cetacei, to the os uteri. I imbedded the os and cervix in this preparation, and passed up a dossil of lint well greased to prevent its coming away. These applications were repeated every two or three days for some time, interrupted occasionally either on account of the catamenia being present, or for the purpose of applying more leeches. The improvement of health, strength, and good looks was very striking; she lost all the sensations and other symptoms from which she was suffering when she first arrived in town, and declared she felt quite unconscious of anything being the matter with her. It now required careful manipulation to distinguish even any portion of the tumour through the abdominal integuments; the cervix uteri and as much of the uterus as could be reached with the finger per vaginam appeared quite natural. The bowels still require careful management to prevent accumulation taking place, which invariably produces symptoms of pain and congestion about the pelvis. She has returned to her home in the West of England, with directions to have the ointment applied from time to time.

My observations on this long and interesting case I must delay until my next report.

SURGICAL CASES.

CASE VI.

Concussion of the Brain, followed by Inflammation —Simple Fracture of the Right Femur.

Robert Fellows, aged ten, from Peel-street, Hulme, was admitted at half-past twelve, p.m., on the 5th of February, 1845, into the hospital, under the care of Mr. Thorpe. He is a stout robust looking lad, of light complexion; his previous general health has been good, having had little ailment except congenital hernia, for which he has worn a truss.

The account given of the present accident is, that whilst he was standing at the edge of some flags in the street, about an hour previous to his admission, some railings and flags fell upon him from behind, knocking him down, and the consequence was that his face and head came with considerable force against the ground. He was perfectly insensible at the time, and was picked up and carried to the hospital, and when admitted presented the following symptoms:—

He lay very still; surface was pale and cold; pulse was weak and frequent; respiration slow; he was occasionally sensible, and answered questions rationally when roused; the pupils were somewhat contracted. He seemed to suffer pain from the wounds. The right thigh was fractured obliquely through the middle third of the bone—it was a simple fracture. The right hand was much crushed and bruised. The face and head were considerably bruised and injured, the skin of the face being lacerated in several points; the left eye was much swollen, and he could with difficulty open it; there were some slight scalp wounds, but no evidence of injury to the cranial bones. He was put to bed, and after a short time ordered to have cold wash applied to the head and face.

6. Has passed a restless night, but is more sensible; had considerable difficulty in voiding his urine; pulse is more full, regular, and 84; surface warmer; respiration natural; tongue slightly furred and moist; anorexia; some thirst; bowels not moved. He complains of pain from the thigh and face, which is more swollen; countenance is flushed, and has some pain in the head.

7. Had a restless night; slept little; had wandering delirium throughout the night, and appears now at times somewhat delirious; pulse is more full, and 100; skin is hot and dry; respiration slow; tongue furred; increased thirst; anorexia; bowels moved; passes urine without difficulty; countenance is more flushed, and he complains of constant pain in the head. There is considerable ecchymosis of the left eye.

Vespere: He has been worse during the day; the delirium has been more severe, and he complains of increased pain in the head; the pulse became quicker and more hard, and there was an increase of pyrexia, with intolerance of light. At four, p.m., he had applied hirudines xvj temporibus.

Emp. lyttæ; pone nuchæ.

R. Mist. antimonialis, ℥xij. ℥j omni tertia horâ sumenda.

8. Was quieter in the night, and apparently asleep at times; but was frequently calling out and delirious; he appears now half conscious, and is delirious, the greater part of the time muttering incoherent sentences; if roused he will occasionally answer rationally; pulse is 116, hard, but compressible; skin hot and dry; tongue furred and moist; more thirst; anorexia; bowels open; passes urine freely. He complains of some pain in the head, but this has been easier since the leeches; pupils are natural size, and act readily; face less swollen; thigh painful and swollen.

Cont. mist. and cold lotion. Enema terebinth. statim.

9. Passed a better night; slept at intervals; was less delirious, and is more rational this morning; he complains of pain in the bruised side of the face, and of some pain in the head; countenance is rather flushed and hot; pupils are natural; pulse is 104, softer and more regular; surface warm and dry; tongue furred; less thirst; bowels open, were freely moved by the enema; passes urine freely; thigh less swollen and less painful.

Cont. cold lotion and mist.

10. Had a tolerable night; was occasionally delirious, but appears rational at present; still complains of the pain in the head; pulse 100, more full and stronger; hot skin; furred tongue; much thirst; bowels freely open. There is less swelling of the face; but it is much flushed and hot; thigh more painful.

Cont. mist., &c.

11. Slept at intervals in the night, but was frequently delirious; he is now more rational, and says he has less pain in the head; countenance is flushed and hot; the swelling of the cheek, eye, and face is less, but the left eye continues much ecchymosed; pupils are natural; no intolerance of light; pulse is 104 and soft; skin cooler; tongue still furred; some thirst; bowels freely open; has slight pain in passing urine. Thigh painful, less swollen. To have hirudines xiv temporibus.

R. Hydrarg. chlorid., gr. j; Pulv. antimon., gr ij. Fiat pulv. Capiat j omni sextâ horâ.

12. He began yesterday afternoon to have pain in the abdomen, which got much worse in the night, and still continues; it is increased by pressure, particularly in the region of the umbilicus; there is no swelling, but the abdomen feels tense; he has some thirst; bowels were freely open, and pain was somewhat easier after this; appetite better; pulse 100, soft and regular; skin cool; passes urine freely, but has some pain in doing so; has some slight cough; has less pain in the head; is free from delirium. The swelling of the face and ecchymosis of the eye are subsiding; thigh easy.

Cont. mist. and pil.

13. Had a better night; the pain in the abdomen is easier; is perfectly rational, and free from pain in the head; pulse 102; less pyrexia; bowels freely open; appetite improving.

Cont. mist. and pil.

14. Continues to improve; has less pain in the face, and the swelling is entirely gone; there is still a little ecchymosis of the eye; bowels regular, free from pain; appetite tolerable; thigh has been easy, swelling has considerably subsided: it was this morning put up with the long splint, extending from the axilla to below the ankle on the outside of the limb.

17. Is daily improving; is free from pain or uneasiness in the head; pulse 98, soft; bowels regular; tongue clean, and appetite good; passes urine freely; thigh has been tolerably easy, and is in good position.

Omit mist. and pil.

21. Is progressing very favourably; is free from pain or pyrexia; tongue clean and moist; appetite good; bowels regular; thigh easy. It was again dressed to day; it is in fair position, and there is some callus around seat of fracture; it was put up again with long splint.

26. Has continued very well until yesterday, when he complained of some pain in the head; this is again subsided; pulse is 95, soft and regular; skin hot; tongue slightly furred, some thirst; appetite tolerable; bowels regular; the thigh is easy, but he has been very rough, and displaced the bandage; it was again adjusted; there is a considerable quantity of callus, and legs appear of equal length.

March 5. Is convalescing gradually; he soon recovered from the slight relapse of the 25th. Thigh is easy, but he is very rough, and displaces bandages.

10. Has continued improving; is free from pain or uneasiness; thigh was again dressed to day; there is a considerable quantity of callus around seat of fracture, which projects much on the outside the limb, and I believe the bones slightly overlap, the leg being somewhat shortened; it was put up with short splints.

17. Continues in good health. Thigh was dressed again; there is some overlapping of the bones, the lower part of the femur resting on the outer side of the upper portion, and giving the limb an arched appearance. It is about one inch shorter than the other leg. He has considerable power

over it, and can bear some weight upon it. It was again put up in short splints, and he was made out-patient, and left the hospital.

REMARKS

At the time this boy was admitted he had symptoms of concussion of the brain, not of a very severe character, but still such as to require careful watching. Injuries of the head, commencing with symptoms of concussion, are sometimes very obscure, the symptoms present being no index of the extent or severity of the injury to the brain or cranial bones, and therefore care should be taken in forming a diagnosis, and our prognosis will be but indefinite in the early part of the case, and ought to be founded only on the future symptoms. This I am convinced of from having seen one or two cases where the injuries were very severe; in one case there was fracture through the base of the skull, and yet the early symptoms were very little more severe than in the present case. The state of the pupil is a very indefinite symptom, as far as I have had an opportunity of observing, in enabling us to distinguish between concussion and compression: but in this case it was contracted, as is usually the case in concussion. The danger of injuries to the head, such as occurred in this case, depends not so much upon the immediate symptoms, as upon what may succeed them. Inflammation of the brain may occur at a very early, or even at a very distant period from the time of the accident, and particularly in young children, where the liability to this is greater than in the adult. In this case, symptoms clearly indicating inflammation of the brain set in, on the second day, such as pain in the head, delirium, quick pulse, some intolerance of light, and pyrexia. After concussion of the brain we should be ever watchful for these symptoms, as indicating the commencement of a rapidly fatal disease, if not checked, and particularly fatal after injuries of the head. The first lot of leeches, with the blister and antimony, relieved the symptoms in some measure but still, although they were not so severe, there remained much delirium, with a quick pulse and pyrexia, symptoms which are very suspicious, as showing that if the brain was not in a state of actual inflammation, it was at least bordering very closely upon it, and it was therefore necessary four days afterwards to repeat the leeches, and to exhibit calomel, which entirely subduedall the head symptoms.

The fracture of the thigh was not put up for nine days after his admission; this is a much longer time than it is well generally to leave similar fractures unput-up, unless there be more injury of the surrounding parts than existed in this case; but it was here thought best not to interfere with it until the phrenitis was subdued; to this circumstance, and to the fact of his being so very restless, it was most probable that the overlapping of the bones, and slight shortening were owing, and not, as some might say, to the kind of splint used, for a more successful plan of treating fractured thighs than with the long splint could not possibly be devised; in fact, if ordinary care be used as to the time and mode of putting them up with this splint, it is very rare indeed that there remains the slightest deformity or shortening of the limb.

REVIEWS.

Lectures on Pulmonary Phthisis, delivered in Jervis Street Hospital: comprehending the Pathology, Diagnosis, and Treatment of the Disease. By JOHN T. EVANS, M.D. Dublin: J. Fannin and Co. 8vo, pp. 196.

In reading the preface to this work, we were somewhat startled by the following novel announcement:—"After all, I have no hesitation in saying that St. John Long was less of a charlatan than many physicians of the present day with an alphabet attached to their names; and if his patients placed unbounded confidence in his skill, the reason was, because he actually performed many extraordinary cures." (p. ix.) Who the physicians are with alphabets to their names, who are less reputable in the ranks of physic than the notorious painter, glazier, and basket-maker, who made his way to preferment by falsehood and fraud, is better known to our author than to ourselves; but we cannot help saying that the discretion is far from judicious which can award praise to the veriest impostor and quack that ever played upon the credulity of the public, or which can place such a pretender for a moment in company with legitimate practitioners of medicine. That he deceived the public into a belief in the virtues of his remedy, is as notorious as that Paracelsus did; and that many cases of bronchitis, which he called consumption, got well under his care, we do not pretend to deny,—nor do we deny that he made a fortune out of the folly of the people—but we must not be weak-minded enough to take popular testimony for our belief in the practical skill of a presumptuous adventurer—or even credit what the juggler said of his remedy, when himself died the victim of the disease which he boasted it could cure.

Our wonderment at the voluntary tribute to the charlatan which Dr. Evans gives in his preface, was explained away by a passage or two which we met with in the body of the work. "In very early life," says the Doctor, "the man who was afterwards so celebrated under the name of St. John Long instructed me in oil painting in my native city. An acquaintance thus sprung up between us, and in some time afterwards, when I went to London, having met him accidentally, we renewed our former intimacy. I now found that he had changed his pursuits, and was engaged in endeavouring to establish his reputation as an empirical curer of consumption. He infected me with his enthusiasm, and, having nothing to do but amuse myself, knowing little if anything of medicine, and not having the most remote idea of ever studying it as a profession, I spent the greater part of my time for some years in assisting him in his daily frictions, and at last became as expert in the operation as himself." (pp. 130, 131.)

Upon this passage we refrain from comment, but we cannot help thinking that if Dr. Evans had reflected upon a certain old adage which speaks of "evil communications," he would have seen the wisdom of forgetting the follies of early life, or at least of not bringing them before the world and the profession as things to be proud of.

From the imaginative style in which certain parts of this book are written, we are afraid our author got a smack of St. John Long's literature, as well as of his painting and medical sagacity. If Charles Phillips had to play the orator upon the march of consumption, he would not beat the following in measured euphony and formal antithesis. "You will see whole families springing up in pride, joy, and hopefulness—beauty in every form and intelligence on every brow. The elder children, full of confidence and gladness, pass the epoch of puberty; they are struck down: others follow in the fatal wake, until some one, or two, perhaps, remain—dejected—timorous—looking for disease in every blast, for death in every shower—and it may be, in a few years, all have passed away, and the parents alone remain, childless, solitary, and heart-broken." (p. 2). If a touch or two from Kirke White had been added as a tail-piece, the picture would have been very pretty indeed.

The following bit of pathos, though laid on with a less liberal brush than its predecessor, is yet much better fitted for a methodist meeting-house than for a work professedly scientific. "The noblest attribute of the science of medicine is that whereby its cultivators are enabled to alleviate human suffering, and to interpose the shield of therapeutics before the threatened dart of death. And if at any time we are enabled to rescue the child of a fond and devoted parent, or the stay of a depending family, from the dark recesses of the lone and silent tomb, appearing in the no distant perspective ready to receive them, we deeply feel at such a moment how utterly insignificant in the comparison are the self-gratulations to which the most brilliant discoveries in the abstract sciences can give rise" (p. 91). To our judgment, it would have been far better, had Dr. Evans occupied half a page by telling us something we did not know. He never can have read Longinus on the Sublime, or he would avoid perpetrating such sins against literary taste.

He tells us that St. John Long knew nothing of pathology, and we are quite ready to believe it, or his pupil would not enunciate such notions as the following:—

"Disease never arises of itself in the living organism; it is always the effect of the influence of external agents" (p. 3.) What would the author make of purulent blood, of tubercle and cancer in the blood, without any organ being affected with the disease? What of scrofulous deposits in the mesentery? What of spontaneous phlebitis?

"It (tubercle) is in fact coagulable lymph." "Many observers have ascertained that lymph can be converted into pus, so that it would appear that tubercle is an intermediate stage in the transformation" (p. 7). Besides the manifest contradiction in these two sentences, we have the novel announcement of many observers having found out that lymph can be converted into pus! Somebody must have been playing a hoax upon the doctor's credulity. We assure him, in all gravity, that no such discovery was ever made by an authority worthy of the least confidence.

"Every case of phthisis pulmonalis commences with bronchitis, active hemoptysis, or pneumonia" (p. 10). "That we deny," as Sterne said of the texts of his sermons. It might be so in St. John Long's practice, but the pathology and practice of our school tell us very different things.

At page 16 we are told of a girl, who, whilst suffering from gastro-enteritis, caught cold, "and very soon after, the fatal *râle* of tuberculisation was heard under the spine of the left scapula." What *the* fatal *râle* of tuberculisation is, we should very much like to know. We know of no sounds that belong to tuberculisation of the lungs, in any of its stages, that are not also manifested in certain other pulmonary affections. If there be any *noise peculiar*, it has hitherto escaped us, and right glad we should be to become acquainted with it.

At page 18 the Doctor says, "Are tubercles in the lungs the cause of phthisis pulmonalis? I think not. When abscess of the lung results from partial pneumonia, we do not look on the pus which it contains as the cause of the disease. Tubercle is only a solid form of pus, and the same reasoning may apply to both these forms of lymphy exudation." This is very funny. In the hands of our ingenious author, tubercle is the most protean-like commodity imaginable. He has before told us that it is lymph, and a something intermediate between lymph and pus, and now he says it is pus solidified! Again, if tubercles in the lungs are not the cause of phthisis *pulmonalis*, we should like to know what is? Predisposition to the formation of tubercular matter, or tubercular diathesis, may be the cause of the *genesis* of tubercle, but if its presence in the lungs be not the cause of the ailment the lungs suffer from in phthisis, then, to our judgment, two and two do not make four.

At page 31, we are informed, "that the existence of tubercles is not signalised by symptoms, nor their absence a cause of amelioration in disease." Does the author then mean to say that if a patient suffer from tubercles in the lungs, and these tubercles become absorbed, he does not get better? And if "the existence of tubercles is not signalised by symptoms," what are we to say of *the* fatal *râle* of tuberculisation?

We are informed at page 114 that Dr. Marshall Hall has shown that an attention to position of the patient in bleeding, will guide as in the amount of blood to be abstracted. We suppose he alludes to the fact of a patient fainting sooner when bled in the upright, than in the horizontal, position, which happened to be the discovery of a no less antiquated personage than Galen!

Amongst the remedies recommended, one is to limit the supply of oxygen to the patient, "by diluting the air he breathes by some innoxious gas;" and amongst other *harmless* things, he advises as "perhaps still better, *carburetted hydrogen*" (p.p. 109, 110).

Did Dr. Evans mean this for a joke, or did he really know no better? Counter-irritation seems to be his great remedy, as it was with the immortal

chest; and himself has often, he says, obtained the best effects from the extensive and regular application of a contra-stimulant, *that had been previously employed in other hands*, for a length of

time without the slightest benefit" (p. 189). This would almost incline one to believe that the Doctor, like the Saint, has got something of a magical touch about him, and that it is not so much to the material used, as to the man who uses it, that the cure of consumption is chiefly due. Errors like those we have pointed out, abound throughout the work, which, however, in certain places, evinces a considerable amount of natural shrewdness and tact. Dr. Evans is clearly not wanting in ability, but he obviously wants more experience in practice, and a better acquaintance with physiology, pathology, and therapeutics, before he can undertake medical authorship with success.

TO CORRESPONDENTS.

Mr. Edwin Lee's paper on Mr. Liston's recent communication to the Royal Medical and Chirurgical Society shall appear in our next.

H. H. *is undoubtedly open to prosecution; being, however, a surgeon, it is improbable that he will be selected in preference to persons in practice without either a medical or surgical qualification.*

X. Y.—*The stramonium cigars are no novelty.*

G. G. *should take his question with a guinea to a medical man. We have no faith in the virtue of gratuitous opinions.*

F. B.—*We shall be happy to publish the case illustrated by our engraver. We shall require drawings as perfect as possible.*

Homœopathy.—*We are very ready to publish Dr. A. Combe's opinion on this subject on the first favourable opportunity. At present space is wanting.*

E. A. T.—*Received.*

X. Y. Z.—*It depends on the way in which it is contracted.*

Mr. John Staples Keddell, of Sheerness, *has favoured us with a letter containing his experience of the conduct of the Poor-Law Commissioners towards medical practitioners. Mr. Keddell has been fortunate in his connection with union practice, and we regret that our space will not permit us at present to make the results of his experience generally known. Mr Keddell's letter is written as an answer to the remarks of Mr. Daniell, contained in our last week's report of the proceedings of the National Association.*

Mr. Mann *is thanked for his communication. Such advertisements are unfortunately very common.*

W. K.—*We are obliged to our correspondent for his criticism, which is just.*

The correspondence between Dr. Handyside and Dr. Mercer is too long proportionately to its importance for our pages. Dr. Handyside being a candidate for the university chair, now filled by Mr. Goodsir, was charged by Dr. Mercer with a breach of a promise of honour, Dr. Mercer having bought an anatomical school of Dr. Handyside on a positive understanding that the latter was never to re-engage in anatomical teaching in Edinburgh. Dr. Handyside denies that there was any such agreement, and Dr. Mercer has no authority for his own impeached veracity but a gentleman who, unfortunately, lives a long way abroad.

Medicus, A Constant Reader, M. D., *and others on the necessity of joining the New Institute shall have early consideration.*

A number of papers have been received, the names of whose authors we do not mention from our fear that we cannot find space for the majority of the communications.

***THE MEDICAL TIMES** is the only Medical Journal published at its own Office, and which is free from the control of all Booksellers and Publishers. Gentlemen may procure it by an order on any Newsman or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfrae, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-Yearly Subscription, 13s.; Quarterly, 6s. 6d.*

THE MEDICAL TIMES.

SATURDAY, MAY 2, 1846.

> In this impartial glass my muse intends
> Fair to expose myself, my foe, my friends;
> Publish the present age; but where my text?
> Is vice too high, reserve it for the next.—POPE.

THE plan suggested by the Committee of the National Association for the re-organisation of the Profession is of so obviously wise and comprehensive a character, that opposition is disarmed. It carries with it the fascination of an Eastern enchanter. Before it the snake has sheathed his sting, and the ass forgotten his bray. Malice sits weeping over her blighted schemes, and Envy gnaws her heart in secret. Discomfited and rebuked, an unwilling assent is wrung from the adversary, and the calumniator confesses his guilt in silence. The juncture is happy. Let all good men unite, and the disinterested labourers in our cause will speedily ensure as great a triumph for the Profession as they have recently achieved for themselves.

We have been, for some years now, engaged in the cause of medico-political improvement; we have seen associated men of all characters and grades of ability; we have become versed in the tactics and discipline of agitation, and familiar with all the subtle intrigues and striking evolutions which often surprise the beholder of the melodrama of public life; and we have come to this deliberate and unchangeable conclusion—that the clamorous champion of public virtue—the unblushing reviler of private honour—the glib professor of personal integrity is, usually, of all men the most sinister, corrupt, and selfish in his heart. It is an old adage, "when a man flatters you, look to your pockets," and it was an expression of the celebrated Dr. Johnson that "patriotism was the last refuge of a scoundrel." Let us beware, then, how we receive congratulations from an enemy, and when an individual suddenly turns patriotic, we must not the less remember that, beaten at all points, he has had recourse to the last refuge of baseness.

While we are thus, on the one hand, performing a cautionary duty, we invite, on the other, the support of every conscientious and liberal man to the proposition of the National Association. During our career we have had frequent opportunities of witnessing the noble ardour and high sense of integrity which animate the Medical Profession of this country; and in now calling upon them to rally round the standard of the Association, we are confident that our cry will meet with a cheerful response. At the late great meeting the announcement of the Committee was received with enthusiasm, and throughout the length and breadth of the land an interest in the labours of the Committee has been awakened, which augurs most favourably for the issue of their great undertaking. We hope we shall speedily find that public meetings, not only of the local associations, but of other members of the Profession, have been held wherever two or three practitioners could arrange a meeting, and that resolutions have been passed to assist, by every means, the accomplishment of the noble enterprise in which the fortunes of the General Practitioners are embarked.

Let no unworthy jealousies mar this movement—let nothing derogatory to our professional character prevent that cordial co-operation which is necessary to conduct our cause to a successful result. Tardiness, lukewarmness, doubt, is now suicidal. Let no malicious insinuations—no equivocal approbation—no cold suggestions—drop into the ear, and chill the hour of action. If each member of the Association will make it his business to obtain only two, or even one more signature, in support of this great cause, the whole Profession will be banded together in one body, and exhibit a moral power that nothing can resist, and that will make success in any legitimate undertaking of the Association unconditional and absolute.

If ever union was necessary, it is necessary now—when success must entirely depend on *voluntary* exertions. Let us not, however, be understood to indulge in that maudlin liberality—that sophistical simulation of candour—that fatal folly of inviting and sanctioning an union of men with a disunion on principle. Such a thing is an impossibility—contrary to experience and common sense—and can end only in ruin. The man who advocates it must be either a fool or a knave—a fool to pin his faith on an absurdity—or a knave to promote his self-aggrandisement by the jealousies, and dissensions that must necessarily result. We know that the hand of fellowship has been professedly proffered on these terms; but we trust that the enlightened intelligence of the Profession will scorn to accept it. There must be a creed to believe in—a banner to fight under: the National Association have unfurled their flag, inscribed with a National Institute; and we trust that all our readers will see the propriety of immediately buckling on their armour and aiding the committee to carry on the warfare. UNITE, UNITE, is indeed the motto; but unite for the accomplishment of a principle, and for nothing else!

Our attention has been directed to a meeting of a few individuals at the Freemason's Tavern, who have constituted themselves at one and the same time a *deputation a committee, and an association! and have appointed in their own persons, presidents, chairman, secretaries, and all the functionaries thereunto appertaining!*

These individuals are, in truth, the Tooley-street tailors of the Profession, the *disjecta membra* of various pre-existing effete bodies, having no principle of association, no bond of union, no assimilating qualities, no common feeling; no common party, and no influence or cause for it, personal or private. Perhaps we have carried the negative statement too far; there may be *one* principle of association, *one* common feeling: but the subject is too ungracious for us to dwell upon. Even now we should not have noticed them, if the Committee of the National Association, with that condescending generosity that has ever marked their career, had not stooped to receive a deputation from this body—the *deputation* being the *deputing* body itself—and had not thus brought their political spumescence for a moment on the surface of the stream.

We hear, however, that in *their two large* PUBLIC *meetings* (of nine and thirteen individuals, respectively) faction has ventured to breathe enmity, though it has not yet dared to speak defiance. They have not, in fact (extremely violent and quarrelsome though they be), a ground of complaint against those gentlemen, to overawe whom they hold their *imposing* nocturnal assemblies. Professing concord and union, they are seeking for the unguarded moment when they shall be able to plunge their weapon deeply into the side of their adversary.

We beg of them to reconsider their position; if they persist in their equivocal, nay, *dishonest*, career, we have a duty which, as journalists and guardians of professional welfare, we shall not hesitate to perform. We know that a few strokes

of our pen would blot out the names of the whole of these gentlemen from the roll of public characters. We refrain: and we only keep our hand raised to give them time for penitence and retreat. Their doings are not unobserved, and whatever their resolutions may express, it is desirable that far more liberality of sentiment should govern their proceedings. If this does not happen, then the press must interfere—

> "A chiel's amang ye takin' notes,
> And faith he'll prent 'em.

Rejecting this unattractive subject, we once more call upon our professional brethren to strengthen the hands of the committee of the National Association. A glorious destiny is before them; and if they now stand listlessly by while the tide of fortune is rising to its flood—for them at least—it may never rise again.

> Despicere unde queas alios, passimque videre
> Errare, atque viam palantes quærere vitæ.
> LUCRETIUS.
>
> ——— Monstrum nulla virtute redemptum
> A vitiis. JUVENAL.

IF we give Hesiod credit for telling the truth, then are we to believe that all the ills that infest us poor mortals are due to that infatuated fellow Prometheus, who was silly enough to open Pandora's box to see what treasure was contained in it. The only treasure it had lay, like treasures in general, deep enough not to be got at, except at a sacrifice hardly worth the making. All over and round about it, nestled, in concentrated snugness, masses of mischief, which bustled themselves into business the very moment they saw daylight—what business they had to do any such thing it does not become us to inquire. Out they came, so says the poet, and began right earnestly to clap their wings, and wag their tails, in an ecstacy of *diablerie*. That they have flown, and fluttered, and dropped their venom, ever since, is well enough known to every poor sinner who has felt the effects of an introduction to this nether earth. Why such things were called into existence, and commissioned to visit us, is an ultimate subtlety that even the brains of Thomas Aquinas could not compass—all we know is, they are here, and precious nuisances we call them. The best proof we can have that nothing was ever created in vain, is in the fact that these said nuisances are not without their claims upon one's gratitude. The proverb says, "It is an ill wind that blows nobody any good"—and so we should think it would be for we have the notion that no hurricane, whirlwind, sirocco, or any such like, ever yet blew without bringing some benefit or other with it; and, therefore, we are prepared to submit that disease, not the least serious of the sins against one's comfort that Pandora had the keeping of, may be a messenger of health to the particular somebodys who make a living by it. Strange enough is it, that the sins and sufferings of one portion of mankind should be so many perquisites to another. Were our *morale* what it ought to be, then would parsons be at a discount, and a precious influx their "turn out" would make into the humbler ranks of society. Were our materiality unblemished and everlasting, doctors would have nothing to do, except like their physic, to go "to the dogs." Sins and sorrows, then, have a good deal to do with the maintenance of a very significant portion of mankind. As for ourselves, doctors we mean, we are so complete a paradox that, *in vita in morte*, should be the motto of our tribe. The antiquated puzzle of one seed dying that another might live, is typified in our case every day. Somebody says, somewhere or other—

> 'Tis nature's law: wave urges wave:
> The coffin'd grandsire seeks the grave,
> The babe that feeds by suction,
> Finds with his ancestor repose:
> Life ebbs, and dissolution sows
> The seeds of reproduction.

So it is with physic—it feeds upon the material that dies and decays before it. It is a singular fact, but perfectly true, and no doubt perfectly right, or there would be no foundation for the philosophical doctrine of sympathy and antipathy.

The physic we allude to, of course, is legitimate, but it is unhappily permitted to be corrupted, and almost as commonly as tares are permitted to thrive amongst wheat. The very distribution of the one furnishes occasion for the dissemination of the other. Good and evil are as constant to one another as the ebb to the flowing of the tide. It would almost seem that, if not in some sort companions, either would be a non-natural. There is no chance, we fear, of having any such monstrosity in physic, for as sure as any in the regular *corps* may pursue a line of lucrative and honourable practice, so surely will one of the un-drilled follow in his wake, and at last out-distance him in the great race of recompense. Assuredly amongst us, the running is not to the swift, nor the fighting to the powerful, for cunning and craftiness have it all their own way; and it were as easy to tie a knot in a sun-beam as for a worthy practitioner to make as short a cut into popularity as a worthless one!

To take a case in point. Blondel, in 1665 brought into notice, or rather, practically revived, the use of arsenic, externally, in cancer. He made no secret of it, but stated openly how the arsenic was prepared, and in what quantity, and in what manner, it should be applied. All this was contained in his book, "De Cura Carcinomatis absque Ferro et Igne." Half the people were afraid of the remedy when they learnt what it was, and, for precisely the same reason, the other half did not think it worth any notice at all. Poor Blondel had the *rare* merit of being honest, and he met with the *common reward*, in such cases, of indifference and distrust. Since his time, a host of charlatans have practised upon public credulity with his very means, and have had their pockets well filled for their presumption. "Cancer curable without cutting" is an advertisement that has paid as well, and been as well paid for, as consumption curable; and yet, in the majority of cases, the despised remedy of Blundel has been the free trap to catch flats with. Both sexes have made it available to their interests, and, actually, an old woman, too antiquated and imbecile for anything but quackery, made it fill her own purse, and furnish a generous settlement upon her children! Sydenham once said, but whether in earnest or in irony we are not informed, when asked by a student what books he should read;—"Oh! why, read Don Quixote, it is a capital book, and one I consult very often." We have our doubts whether Sydenham ever said any such thing; for we suspect his memory to be as much traduced by medical *bon mots*, as is Sheridan's by those of jollity and *belles lettres*; but the fact being admitted, it has furnished proof enough that, "monkeys mostly out-ape us, commit what absurdity we will." If Sydenham said what is imputed to him, he did it out of that contempt for presumptuous authorities, which any one of his genius and judgment might unhesitatingly entertain. With Sydenham, as with Shakspere, "none but himself could be his parallel;" but plenty since his time have seized upon his license, and taken abominable liberties with it. A common trick amongst men who know nothing of medical practice is to deride it altogether, and affirm, that patients will get well as readily without physic as with it. This is a threadbare sort of cloak to cover ignorance with; but yet, there is many an impostor who, now-a-days, covers himself with the unseemly garment, and finds himself comfortable in it. We have met with many such, and have enjoyed their affected scepticism right heartily. Another class, utterly unread in the profession, and, of course, in happy ignorance of the *status* that it had, or that it has, pretend, like the empirics of old, to care nothing for authorities, but rely wholly upon experience. They despise books, because they have got none; and the information contained in them, because they have never been guilty of gathering it; and thus, floundering away in the mud of their making, they affect to be wiser than their neighbours, by virtue of reading only, what they call "the great volume of nature." Were it possible for such commodities ever to arrive, single-handed, at anything like tolerable medical knowledge, we might be tempted to inquire, how many lives had to be forfeited ere they were fit to be called practitioners? Many must be the victims sacrificed at such a shrine, ere it could b considered worthy. Pretenders of this class are unhappily, numerous, even now, in the face of the light of science; luckily, however, the darkness they create is fast being dissipated, and though themselves may not be banished from our brightening region, at least we have the consolation of being able to recognise their presence in the shadow that pervades it.

Sydenham had a particular mode of practice in a disease which has long been the opprobrium of our profession, and which has furnished as much food for quackery to feed upon as any other ailment known in the great mart of physic—viz., GOUT. Up to the time of our English Hippocrates, the chief remedies in this "terrible trouble," were, the cold water of Kinglake (hydropathists fancy they are novel in their absurdity), the *eau medicinale* of the French, and "patience and flannel," the veritable commodity of fools of all sorts. Against these farragos Sydenham invectively set his face, and struck out a middle line of treatment, compounded of "gently stimulant," "antiscorbutic," and "purifying" medicines. His practice was very successful, though himself fell a victim to the disease for which he had prescribed, and upon which he had written so lavishly; but no sooner was he "quietly inurned," than, with the celerity of a trick in a pantomime, did his triune mode of practice resolve itself into its elements, and from each sprung a systematic, substantial quack, who boasted himself to be the successor, in all potency, of the illustrious Sydenham! Pandora's box was certainly very bad, but it could scarcely have been worse than this, had it had only one mischief to meddle with. "This was Sydenham's practice," said the angelica-root man. "No, this was his plan," said the fellow with the wormwood; "nonsense," said the vendor of comfrey and chamomile, "mine is the recipe that will relieve you in a twinkling." It will scarcely be credited, that, within a quarter of a century of the death of Sydenham, three large fortunes were made, out of the credulity of the English people, by idle adventurers, who seized upon his particular tenets to make separate merchandise of! Gout cured this way, and gout cured that, and gout cured the other, were so many highways to wealth, assailed by three rascals who "ran a muck" upon the credulity of the people, and found themselves finally rewarded for the experiment

they had risked. Even to this day, Sydenhamites are to be found, practising some particular branch which its originator would have rejected singly, whilst the "patience and flannel" men come in cloaked in the absurdities of yore, and as effectually concealed from common scrutiny as were the primitive craftsmen of their calling.

The catalogue we have given of ancient quackery is merely a compendium of what we had once designed to give. The scale is a mighty one, and we have been compelled to pass over certain periods of time whose history would have given us ample materials for reflection. Instead of treating specifically upon the quackery of the ancients, we have chosen rather to treat of that part of it which bears a relation to the idle empiricism of the present day. We have taken the more prominent cases, because they are best deserving of our notice; but, did our time permit, we could go over the whole range of modern quackery, and prove, not only that no part of it is novel, but that its absurdity was proven to demonstration long before the people of this planet had attained to the wisdom they now profess to have.

TRANSACTIONS OF LEARNED SOCIETIES.

PATHOLOGICAL SOCIETY OF DUBLIN.

Meeting of March 7th, 1846

Dr. Green in the Chair

Dr. Law said the pathological specimen he had this day to exhibit had been taken from the body of a young woman, who was admitted to Sir P. Dunn's Hospital on the 27th of February, and died in four days after. Only a very imperfect history of the case could be obtained, for the patient's mind was wandering on her admission, and besides, she was brought to the hospital by a man who did not know much about her, but from all that could be gathered, it appeared that her illness was of eight days standing, and had commenced with shivering, consequent on exposure to cold. A severe attack now followed, the symptoms when she came under observation being as follow —Her mind in so unsettled a condition, that, as he had just observed, it was impossible to get any detailed account of her illness; she was not long in hospital, however, when diarrhœa set in, together with involuntary discharges. The pulse was extremely rapid, amounting to 140, and presenting the character to which the term dicrotous is applied; the heart's action was also extremely feeble, and the countenance had a leaden dusky hue The abdomen was not tympanitic, or at least very slightly so, and was not painful on pressure. There was no gargouillement over the ilio-cæcal region, nor were there any of the spots which are usually sought for in cases of typhus fever accompanied with diarrhœa. For the four days she was in hospital previous to her death, she was gradually sinking, and though Dr. Law did not at all expect her to recover, yet he calculated on the case being a protracted one, and was rather surprised at finding her dead on the 30th, on which day she was seized with a sudden attack of dyspnœa; a considerable quantity of blood frothed from her mouth and nose, and in an hour after she was dead.

On examining the chest, in order to find some clue to an explanation of the cause of death, the substance of the lungs was found infiltrated with blood, constituting a very unequivocal specimen of pulmonary apoplexy. Dr. Law had never seen, he said, nor was he aware of any case having been recorded, in which both lungs were engorged as in this case; one, however, being much more infiltrated than the other. The heart was next examined, having in view the fact of the frequent coexistence of cardiac disease with pulmonary apoplexy, but no trace of disease was discoverable in that organ. The mitral valve was in a perfectly healthy state, and here he would direct the attention of the Society to the remarkably strong and firm condition of the muscular substance of the heart in this case. The intestines next came to be examined, and in them Dr. Law observed there was particularly well marked that species of lesion usually associated with a particular type of fever. The stomach was first cut into, and the small intestines opened from it, and the examination of these had proceeded a considerable way before any unusual appearances were met with, but after a time there were first observed the patches which he now pointed out; masses of glands very much in relief constituting a sort of elliptical arrangement, whose long axis corresponded with the length of intestine, and only appearing more in relief than natural; but as the examination proceeded along the tube these glandular masses became still more prominent, so much so, Dr. Law observed, as to resemble closely the prominences of condylomata; there was yet, however, no destruction of the mucous membrane The patches varied in size, some being of a circular, others of an oblong shape, and presenting in some places the elevated edges and depressed centres of the small-pox pustule; still advancing, we come to patches in a state of ulceration, presenting elevated margins and jagged and broken down surfaces, having some of the matter of the intestine entangled with them. The nearer the termination of the ilium was approached, the more numerous and large did these ulcerated spots become; their surfaces appeared to be made up principally of cellular tissue in a state of mortification and slough. In passing from the termination of the ilium to the large intestines, these diseased appearances seemed to cease almost altogether. On the cœcal aspect of the ilio-cœcal valve there were slight traces of disease, but in the large intestine itself scarcely any at all, there being occasionally only discoloured patches to be met with. The state of the mesenteric glands, Dr. Law observed, was also worthy of attention—in the immediate proximity of the ulcerated patches those glands presented an exceedingly enlarged and reddish appearance. Dr. Law was glad, he said, to have an opportunity of showing to the Society the present specimen, one similar to which he had not seen for some years; it was interesting besides, he considered, illustrating, as it did, so very well those pathological conditions which have attracted so much attention, and respecting which so great a difference of opinion exists.

The continental physicians, viewing this lesion in the light of the cause of fever, wished to expunge the term typhoid fever, and to substitute for it gastro-enteritis, &c. But in this country, although this lesion has been often observed, yet many other lesions have equally presented themselves, and in all the fever exhibited, a certain degree of uniformity, diversified only by the local lesions, which seldom were observed very early in the fever, at least until it existed for some time. He had never known he said, a similar amount of disease detected after so short an illness, as had occurred in this woman, who died on the eleventh day of the attack. It has been stated by Louis, Dr. Law remarked, that he had always known this species of lesion to be accompanied with considerable tympanitis, diarrhœa, and gargouillement, over the ilio-cœcal region, together with red spots on the surface of the abdomen; but in the present case all these symptoms, except the diarrhœa, were absent.

Mr. Hamilton exhibited a preparation taken from the body of a person who had passed fæces from the bladder.

He was attended by Dr. Nulty, and had been seen at different times in consultation by Sir Philip Crampton, Sir H. Marsh, and Mr Hamilton.

The patient was sixty-three years of age, not emaciated, but presenting the peculiar pulse and sallow aspect that persons affected with cancerous disease often have. When Mr. Hamilton first saw him, in June last, he complained of pain and frequent desire to pass water, and, on examining the latter, yellow feculent matter was seen at the bottom of the vessel, and shreds of the same material floating about in the urine. He had been ill for some time, but had only a few days before felt a sense of uneasiness and weight referred to the bladder, soon after which the urine deposited a thin puriform matter, and then followed the feculent discharges from the urethra. The symptoms suggested the supposition of an abscess in the prostate having opened into the bladder, and then into the rectum, establishing a passage between them; but on examination nothing morbid was discovered in the prostate, which, though rather hard and enlarged, was not more so than is usual at his time of life; besides, no urine was observed to come by the rectum. Sir P. Crampton and Mr. Hamilton then formed an opinion that some malignant disease existed, causing a communication between the bladder and rectum, but they did not venture on a more specific diagnosis. Mr. Hamilton washed out the bladder with a little tepid water; but this was followed by so smart a hemorrhage that it was not repeated. The passage of fæces from the bladder continued for a considerable period, attended occasionally with a good deal of uneasiness, but at other times the urine became pretty clear. The patient experienced much relief from injections of tepid water into the rectum.

Last summer he was attacked with apoplexy, the state of coma lasting several days, and attended with some fever; he got completely over this, but the feculent discharge from the urethra continued. He next became affected with cough, and latterly with severe fits of dyspnœa, and the pulse was feeble and very *irregular*. Three days ago he was seized with a second fit like that which had occurred in the summer, and Mr. Hamilton went with Dr. Nulty to see him; but he was just dead when they arrived.

The autopsy very satisfactorily accounted for the feculent discharge from the bladder during life. Corresponding to the termination of the sigmoid flexure of the colon, and commencement of the rectum, there was a scirrheus contraction, formed by the deposition into the sub-mucous cellular tissue of a layer of hard scirrhous substance, of a bluish-grey colour, crossed by a stratiform arrangement of fibres at right angles to the bowel, about an inch or more in thickness at the seat of the stricture, and gradually getting thinner. It appeared a beautiful specimen of the disease so well delineated by Carswell and Cruveilhier, and so often seen in the sub-mucous cellular tissue of the pylorus. The contraction was so great in one part as with difficulty to admit the little finger, and about a quarter of an inch above this the mucous membrane formed a projection, constituting a kind of valve, above which the fæces lodging had caused ulceration, with inflammation of all the tissues of the bowels, and adhesion between the serous portion of the rectum and bladdder An abscess had formed, which, working its way down, had opened into the bladder at its back part, explaining the passage of pus which first took place. The opening between the bowel above the stricture, and the bladder, was not direct, but a long sinuous passage two or three inches in extent, and so narrow that, though the bladder contained much fæces, it was not without difficulty that the opening into it was discovered. The long narrow valvular nature of the communication also explained the fact that no urine was observed to pass by the rectum, as the effect of the distension of the bladder would be, as in the case of the uterus, to close the opening, and prevent the passage of fluid through it. The mucous membrane of the bladder was very little redder than natural. Near the opening from the bowel was another blind one, leading for a short distance between the two cavities. One very remarkable feature in the case was, that during the whole illness, from June to March, the patient never had a symptom of obstruction of the rectum—a circumstance which Mr. Hamilton thought might be explained first by the narrowing still having space enough for the passage of a certain bulk of fæcal matter, but chiefly to the fact of the bladder having acted as an evacuant of the contents of the bowel, thereby lessening the pressure of a mass of impacted fæces on the stricture, and the consequent irritation. The lungs were slightly emphysematous and congested, and there was some hydrothorax. The liver was larger than natural, but not apparently changed in structure. The left ventricle was hypertrophied and dilated; the right ventricle not dilated, but more fatty than usual; there was no valvular disease.

Dr. Lees presented to the Society a specimen taken from a man who died at the Meath Hospital during the foregoing week; he considered it pe-

culiarly interesting from the combinations of disease that were found to consist in the case. The subject was a butler, aged sixty-five, who was admitted to the hospital labouring under jaundice, and at this time appeared in an almost moribund condition, so much so that Dr. Lees was requested by his friends to see him as soon as possible. He was universally jaundiced of a yellowish green hue, and complained of pain in the right hypochondriac and epigastric regions, in which locality a tumour, or rather a general enlargement, was observed, slightly tender to the touch, and extending as low as the umbilicus; vomiting and hiccup were present, and the bowels constipated; there was no ascites, nor pain in the shoulder; the history of the case was on the whole rather obscure. He stated that he had not been addicted to drinking, but complained for the last twelve months of a bad stomach, and only for the last three weeks felt pain, since when he had been jaundiced. From the peculiar green colour of the latter, the great emaciation, the age and general appearance of the patient, it struck Dr. Lees that malignant disease existed, and that the liver was the seat of it; but, on further examination, doubts arose on this point, as the signs and symptoms might be accounted for by a chronic duodenitis with enlargement of the liver. All the bearings of the case being considered, however, it was concluded that palliatives were the only means adapted to it; and, by the use of effervescing draughts, and small doses of the ext. taraxici, the vomiting was allayed, but the man gradually sunk.

Some very interesting facts were disclosed by the dissection. On opening the abdomen, the gall-bladder was seen enormously distended, so much so as to extend down into the right lumbar region, occupying the position of the right kidney. Proceeding further, the stomach was also observed to be very much enlarged; passing down to a level with, or even below, the umbilicus. The liver was also greatly increased in size, and pushed forward, not from any morbid deposition, but from general hypertrophy of its substance. A remarkably good specimen of scirrhus of the pancreas was next discovered, the concave portion of the duodenum being filled up by a large encephaloid mass, and the mucous lining of this portion of the intestine destroyed, the diseased head of the pancreas formed the base of the intestine. The entrance of the common duct was permeable, but the duct itself was distended to such a degree as to have appeared, at first sight, like a portion of small intestine; it was, in fact, Dr. Lees remarked, much thicker than the adult thumb. The diseased condition of the pancreas, Dr. Lees observed, was extremely interesting; during the ten days the patient lived in the hospital, no appearance of salivation manifested itself; this was a point he considered worthy of observation, inasmuch as the occurrence of profuse salivation had been laid down as characteristic of disease of this organ; the man did not complain of ever having suffered anything of the kind.

Another lesion, Dr. Lees remarked, yet remained to be noticed; the stomach, as he had observed, was greatly distended, and was found to contain a fluid of peculiar character, which had been examined by Mr. More, the chemist; but neither by the microscope nor by chemical analysis was he able to detect the slightest trace either of blood or of bile in it. A very interesting specimen of the chronic ulcer of the stomach was also discovered in the usual situation between the lesser curvature and pylorus; it was an exceedingly well marked, deep, excavated ulcer, single as regarded its size, but in the immediate neighbourhood were one or two superficial ulcers in the early stage. The edges of the large ulcer were thin, and formed by the prominent mucous membrane, the base by the vascular coat.

The case, Dr. Lees thought, was possessed of many interesting features, fully sufficient to warrant him in bringing it under the notice of the Society. The man, as he had before observed, though labouring under those manifold lesions, yet, when he came under observation, complained of little or nothing, more than mere debility. A question might arise as to whether the disease of the stomach was of the same character as that of the duodenum and pancreas; but it was quite clear, he thought, that there was no ground whatever for entertaining such an opinion, for the ulcers possessed all the characters of the simple chronic ulcer of the stomach There was deposited in the liver one of Far's tubercles, analogous to the disease of the pancreas and duodenum, and probably secondary to the disease in these parts. Had the man lived long enough, masses of the same malignant growth would, no doubt, have been scattered through various parts of the body, and the ulceration of the stomach would also, it may be supposed, have gone on to perforation, as occurred in two or three cases brought forward at the Society last year, and in which, as so generally happens in such cases, the symptoms were so obscure that little or no pain was complained of until the severe pain which ushered in the violent and acute attack of peritonitis which caused death.

Dr. Hutton exhibited to the Society a specimen of diseased brain, the subject of which was a young woman of phlegmatic and unhealthy appearance, who came to the Richmond Hospital for the purpose of being operated on for entropion of the eyelids, which had produced opacity of the cornea. She was admitted three days previously, having made no mention of any other complaint. While Dr. Hutton was going through the ward yesterday, this patient was suddenly seized with a fit; she became insensible; the breathing slow and laboured, inspiration being attended with stertor and expiration with moaning. The muscles were rigid and the extremities fixed, but there was no convulsive motion of the limbs; the face was swollen and suffused; the pupils fixed and dilated; the pulse was weak, and the surface rather cold; she had vomited a short time previous to the fit. From this she gradually recovered, and spoke rationally to those around her; but she was seized soon afterwards with a second, and again with a third, attack, in which she died.

Dr. Hutton was informed by a patient in the same ward, that the deceased had said she was subject to fits, and it appeared that she had for two days previously, occasionally vomited her food and drink, and had felt pain in her head, of which, however, she had not complained to Dr. Hutton or the resident pupil.

At the post-mortem examination, on proceeding to examine the brain, it was observed that when the cranium was opened the dura mater had a remarkably dry appearance, and on raising this membrane the brain started up as if it had previously been much compressed; its vessels were not congested; there was no opacity of the arachnoid membrane, nor any sub-arachnoid effusion, the sulci between the cerebral convolutions not being less deep than usual; the lateral ventricles contained three or four ounces of serum, and seemed considerably dilated. In other respects the cerebrum was of a healthy appearance and consistence, but in the left lobe of the cerebellum was found a cavity or cyst containing about an ounce of serum, lined with a smooth membrane, and not communicating with the fourth ventricle. In the substance of the cerebellum, and projecting into the cavity described, was a tubercle which exactly resembled the encephaloid, flesh-coloured tumours of the brain, which he (Dr. Hutton) had exhibited on a former occasion to the Society. He remarked that in the present case the disease of the cerebellum had probably been of some duration, and it was worthy of observation that, previous to the last fatal attack, this patient had not only manifested no impairment of sensation or intellect, but the locomotive powers which are said to be regulated by the cerebellum were duly exercised, and indicated no defect, notwithstanding the imperfect and morbid condition of so large a portion of the cerebellum. Although there was a considerable quantity of adipose matter throughout the body the mammæ were as little developed as in a male subject, the uterus was of small size, the ovaries, &c., natural, and the function of menstruation had been regular.

The cause of death seemed to be the sudden effusion of serum into the ventricles—a true serous apoplexy, or water stroke, unattended with congestion of the vessels of the brain, extravasation of blood, effusion of lymph, or any other sign of inflammation.

The cavities of the chest and abdomen presented no morbid appearances.

MISCELLANEOUS CORRESPONDENCE.

THE *SHAM ASSOCIATION* OF "*ASSOCIATED* SURGEONS."

[To the Editor of the Medical Times.]

SIR,—In the short notice you deigned on my letter on the above subject, you made the mistake of treating the meeting with contempt because, though called by public advertisement, only "*thirty*" persons were present. You made here a serious mistake. The number present, instead of being "thirty," was—THIRTEEN! You mistook my writing. * * *

M.D., A SUBSCRIBER.

[Our correspondent, who is rather wordy, quotes a showy advertisement, in large—extra large—print, in the columns of the Lancet (weekly periodical), which made known—we beg pardon, which advertised—still more unfortunate—which was *intended* to make known and advertise—the fact that such an important public meeting was to be held. Mr. Wakley was to be present. He was present; so was Mr. Hodson Rugg, and ELEVEN other gentlemen! But we have said enough.]—ED.

KING'S COLLEGE.

MEDICAL DEPARTMENT.

The annual meeting of this department of the College for the distribution of prizes, and certificates of honour, to the successful students, was held in the theatre, on Saturday. There were present on the occasion the Lord Bishop of London, the Lord Bishop of Lichfield, Sir Robert Harry Inglis Bart.; the Rev. Doctor Sheppard, Joshua Watson, Esq., Doctor Jelf (principal), Doctor Todd (the dean), and the several professors of the department, in addition to a large assemblage of ladies and gentlemen relatives and friends of the pupils, who took an interest in the proceedings of the day. In the absence of his Grace the Lord Archbishop of Canterbury, who was unable to attend through indisposition, the chair was occupied by

The Bishop of London, who said, that having hitherto been accustomed to see the Archbishop of Canterbury presiding at their annual meetings, his absence on that occasion must of course be a subject of regret to them all, more particularly when they were aware that he was kept away by indisposition. They were all aware of the object for which they were there assembled, and as it would be fully entered into in the report that would be made to the meeting by the Dean, he would not detain them longer than to express his satisfaction at the advancement the King's College had made, and the character which the students had acquired, which he attributed not only to the superior education which they were receiving in science, but to the sound principles of Christianity in which they were trained. At the request of his Lordship

The Dean of the Medical Department then rose and said—My Lord, it is my duty to inform you that this is the fifteenth distribution of prizes in this department of the college and it is almost needless for me to add how much this ceremony is solemnised by your Lordship's presidency, or how greatly the value of these prizes, which my young friends will this day receive, is enhanced by their being received from your Lordship's hands. The report, which it is my duty to make to your Lordship, embraces the following topics:—

"The number of students attending the medical classes, their conduct during the past session, the general state of the medical department of the college and of the hospital, together with a statement of such events or changes, affecting our government of the college, as may have occurred during the past year.

"The number of the students attending the medical classes exceeds that of any previous occasion.

"Those who have been matriculated and take their entire medical education at the college are 192 in number, of whom 183 are in actual attendance.

"The occasional students who attend only one

or more courses are 22, making a total of 211, of which number 160 attend the hospital.

"It will be interesting to your Lordship to know that each succeeding year we find, in the medical department of the college, a greater number of students who have previously enjoyed the advantages of one or more of the other departments of the college. Many have been brought up in the school, and not a few have attended the course of instruction in the department of literature and science. We have more than one associate of the department of general literature pursuing medical studies. One of the junior scholars, whom I shall have to present to your Lordship to-day, has passed through a career of distinction in the department of general literature; and the gentleman who has obtained the Medical Society's prize is now a distinguished student of the same department.

"We are thus enabled to see the mutual bearing of the various departments of this great college, which now numbers very nearly one thousand pupils receiving instruction within its walls, one upon the other. The school supplying the senior departments, and the department of general literature and science sending forth its pupils into the various callings of life.

"It is extremely gratifying to me to be able to report to your Lordship most favourably of the conduct and diligence of the medical students. It is but rarely that I have been called upon to take any notice of misconduct or neglect of duty, and I am happy to add that, when I have interfered my remonstrances have been received in a proper and becoming manner.

"The general condition of the college, and its appliances and means of instruction, exhibit a progressive improvement. Under the direction of our new curator, Mr. Masters, the museums are being put into a more efficient condition, especially as regards the zoological collection, which had hitherto been much neglected.

"Valuable additions have been made to the departments of mineralogy and geology by Major Cautley and Professor Jones, the former of whom has presented his Indian collection.

"The botanical museum has been enriched by valuable presentations from Mrs. D'Oyly and Professor Royle, to the former of whom we are indebted for a nearly complete series of British plants, contained in a handsome cabinet.

"The rooms provided for students within the walls of the college have been fully occupied, and almost exclusively by medical students; and from the communications which, in my official capacity, I have had with parents, I am able to state that, had the means of accommodation been much greater, there would have been no lack of tenants

"I must remark, that the advantages which the resident students of this college enjoy are very great. They have good and well-ventilated rooms, sufficient attendance, and every convenience that can be reasonably required; and all this at a charge which, although now moderate, may, I hope, be yet materially reduced. They have the benefit of the superintendance and advice of a resident medical tutor, and they are under the immediate supervision of our kind and excellent principal.

"A recent occurrence of a very afflicting kind has forcibly impressed me with the advantages of a residence within the college to a youth who is away from home, and whose friends and relations do not reside in London. One of the most promising and most diligent of our students was struck down by a severe illness, and, in consequence of a rapid and extensive inflammation of the lungs, was carried of in a few days. I had the means of knowing that during the brief period of his illness he could not have been more closely attended to had he been in the bosom of his family. (Applause). He occupied a remarkably well ventilated room; from the commencement of his illness he was attended with care and judgment by the resident medical tutor, Dr. Johnson; he was visited by the principal; and his fellow students who occupied the neighbouring apartments, vied with each other in rendering him assistance. It will be no small consolation to the highly respectable family of Mr. Dennis to know that everything [wa]s done to stay the progress of his fatal malady, [an]d that he wanted no comfort which kindness [co]uld suggest, or friends supply.

"I regret that I am not able to state that there [ha]s been any increase in the accomodation for [res]ident students; but I trust that there can be [no]w little doubt of the speedy accomplishment of [wh]at which has been so long needed

"At the beginning of the session, a plan was [su]bmitted to the council, by which our accommodations for resident students would be doubled, at [a c]ost which the architect of the college estimated [at] £2,600. The council consented to advance [£1,]000 towards this work, provided the remainder [of] the sum could be obtained from other sources. [I a]m now authorised by one who has already been [a] great benefactor to this institution, and who has [ta]ken a special interest in this particular object, to [of]fer the sum of £1,000 for this purpose, and the [fu]rther sum of £300 provided the council will un[de]rtake to complete the required outlay.

"The hospital, which has now become an es[se]ntial part of the medical department of the [co]llege, is steadily advancing in public estimation, [an]d whilst it continues to afford its advantages to [th]e poor, it present an excellent field for the ob[se]rvation of disease to the students who make [go]od use of it. The number of patients registered [in] its books during the past year, exceeded that [of] the former year by 3,000. Although the funds [of] the hospital have not increased in a correspond[in]g proportion with the claims of the sick upon it, [th]is has not been for want of a lively interest in its [b]ehalf from many benevolent friends. It would [b]e ungrateful not to acknowledge, in the warmest [m]anner, the valuable assistance of its many benefactors, and the exertion of many of the committee [of] management, especially of the gentlemen who [ha]ve filled the office of deputy-chairman, Mr. [S]imon, Major Moore, and the present occupant of [th]e chair, Mr. Sambrooke. Established only seven [y]ears, the hospital has now an income, derived [fr]om annual subscriptions alone, of £1,270 per [a]nnum, and to this there has lately been added a [c]ontribution of £300 per annum from the funds of [th]e Holborn estate.

"The great increase in the number of applicants as rendered it absolutely necessary no longer to [d]elay the enlargement of the hospital for the re[c]eption of a greater number of both in and out [p]atients. The committee of the hospital have ac[c]ordingly entered into the arrangements for the [p]urchase of a large piece of ground in the neigh[b]ourhood, upon which the necessary buildings can [b]e erected. Their future appeals to the public [w]ill, therefore, solicit not only annual contribu[tio]ns for the support of the institution, but dona[tio]ns towards a building fund.

"Public attention has been a good deal attracted [to] the need of improvement in the vicinity of the [si]tuation in which King's College Hospital is [si]tuate. I cannot avoid expressing my conviction [th]at there is no part of London where improve[m]ents, calculated to afford great public con[v]enience, could be effected at a more trifling cost. [T]he step which the committee of management has [ju]st taken in the purchase of the large piece of ground to which I have referred, will, I have no doubt, pave the way for these improvements; and their project is, on this account, the more deserving of the liberal support of the public. (Hear, hear.)

"I have now, my Lord, to refer to the most important event which has occurred during the last year, as affecting the department which I have the honour to represent. I allude to that extremely wise measure lately adopted by the Council, of founding scholarships for the encouragement of diligent students in all the departments of the college.

"At the same time I must, with all humility, claim for the medical department the merit of having originated these endowments in King's College. In the year 1811 a proposal was made to the council for the establishment of two scholarships, each of the value of £10 per annum, provided they would endow one of the same value. This proposal was assented to, and at the distribution of prizes, in 1842, I had myself the honour of presenting his Grace the Archbishop of Canterbury, not only the first scholar in the medical department of King's College, but the first scholar connected with any institution for medical education.

"By the late liberal resolution of the council, six scholarships have been established for medical students of the first year—two for those of the second year—in addition to those previously established for those of the third and fourth years; in all, eleven scholarships for the encouragement of medical learning.

"Let us hope, my Lord, that some modern C[a]ius or Radcliffe may be moved to add to these e[n]dowments for the good of that science whose aim is to diminish or relieve the numerous ills to which fl[e]sh is heir.

"The conditions under which these scholarships m[a]y be obtained have immediate reference to the e[n]couragement of the students to pursue the c[o]urse of education which has been laid down for t[h]em by the Professors of this college, a course w[h]ich I firmly believe to be admirably well suited t[o] promote their best interests in a professional p[o]int of view. But there are other conditions b[e]sides those of a purely medical kind. They are s[u]ch as will satisfy us that the candidates for these s[c]holarships have not neglected studies which h[a]ve reference to their highest interests and that t[h]eir education has been conducted so as to enable t[h]em to cultivate general literature with some h[o]pe of pleasure and profit to themselves.

"In conclusion, I cannot avoid congratulating y[o]ur Lordship, who has been the zealous and e[f]ficient Chairman of the Council, and the other d[i]stinguished members of that body, on the present e[f]fective and prosperous condition of the medical, a[n]d of the other departments of this college. And I h[o]pe I may be excused for remarking, that whilst t[h]e last few years have witnessed much angry dis[c]ussion upon what has been called medical reform, w[h]ilst a Minister of State has failed in his efforts t[o] introduce more generally improvements into m[e]dical education, those who administer the a[f]fairs of this college have, unaided by state p[a]tronage or by large pecuniary endowments, f[o]unded and brought to maturity a system of m[e]dical instruction which has not only wrought t[he] most beneficial influence upon the alumni of [o]f the college, but has diffused a spirit of improve[m]ent throughout all the metropolitan establish[m]ents for medical education; the changes in which, [w]hether existing or proposed, are all in the spirit, and in imitation of that system which, by the fostering care of your Lordship and the Council, has been now for many years successfully pursued at King's College.

"In 1831, the college was first ope[ned m]atriculated medical students were required to [c]onform to collegiate rules, and shortly afterwards [t]he "Leathes" and "Warneford Prizes" were [i]nstituted for the encouragement of religious [k]nowledge.

"In 1836 rooms were provided for the residence [o]f the medical students.

"In 1841 the three senior medical scholarships [w]ere founded.

"In 1842, during the principalship of a Right [R]everend Prelate (the Bishop of Lichfield) whom [a]ll who have had any connection with the college [m]ust ever regard with feelings of the most affec[ti]onate respect and regard, a medical dean was [a]ppointed for the immediate supervision of the [m]edical department.

"In 1843 a resident medical tutor was appointed; and, in the present year, eight new scholarships have been founded, in addition to those already existing.

"I have now to present to your Lordship five gentlemen, to be elected scholars of this college."

The successful candidates, whose names are given in another column, were then presented to the Right Rev. Chairman, who briefly addressed them in an appropriate manner on the distinctions they had obtained in that college, and expressed his hope that these honours would prove an additional stimulus for greater and more persevering exertions, the real advantages of which would only become fully known to them in their career in after years.

A vote of thanks was to the chairman, and the meeting separated at five o'clock.

GOSSIP OF THE WEEK.

APOTHECARIES' HALL. — Gentlemen admitted Licentiates on the 23rd of April, 1846: Henry Daubeny, Charles Lowis Norton, Charles Nattrass, Henry Beckwith, Robert Samuel Thornley, Richard Barnes Roscow, William Brinton, Edward Hull, Andrew Truelove Edge, William Evans, Edward Reckitt, Edward Whately.

M. Roden, a pharmacien at Lenzburg, states that leeches may be preserved by immersing them for ten minutes or a quarter of an hour, in water containing from three to four drops of liquid chlorine in the forty-eight ounces.

Dr. Labat, principal physician to the Shah of Persia, and surgeon-in-chief of his armies, who has recently arrived in Paris, attained his position in Persia by curing the Shah of gout, to which it appears he was much subject. He was appointed successively mirza, bey, and Khan, and ranks immediately after the princes of the blood royal.

The sum of 48,000 francs has been demanded from the government by the dean of the Parisian faculty of medicine, to construct a ward in the proposed Hôpital des Cliniques, to contain twelve beds, for the use of sick medical and law students. The conseil academique, and the conseil royal de l'université support the demand.

The cholera, it appears, was introduced into Persia, by the caravans of Steret into the Khorasan, and has passed thence southward to the Kerman, and onward to the marshy plains of Massendheran and Ghilon, where its ravages were very extensive. At Mesched one-third of the population has perished; and the population of entire quarters has disappeared at Teheran and Ispahan.

GOVERNMENT LUNATIC ASYLUM.—The Board of Ordnance having decided on appropriating the large and extensive building on the Denes, near Bury, originally built for a naval hospital at a cost of £120,000, for the reception of lunatic military officers, it is expected that about two hundred of these unfortunate gentlemen will be shortly removed there, upwards of £3,000 having been expended in making the establishment as complete and comfortable as possible. Some of the rooms are fitted up in an elegant manner, and several are padded all over for the more dangerous class of lunatics.

MIDDLESEX HOSPITAL.—The annual distribution of prizes at this school took place on the 9th ult., on which occasion Mr. Hunt, the treasurer of the hospital, presided. After an able address on the state of the school by Mr. Arnott, the chairman of the school, the prizes and certificates of honour were awarded to the following gentlemen:—Medicine—first prize: Mr. A. D. Home; second ditto: Mr. Sydney G. Bousfield; certificate: Mr. Augustus Grant. Surgery—prize: Mr. Bousfield; certificate: Mr. Grant. Physiology—prize: Mr. Bousfield; certificate: Mr. Boyers. Anatomy—prize: Mr. Boyers; certificate: Mr. Pates. Materia medica—first prize: Mr. Boyers; second ditto: Mr. Clapham. Chemistry — prize: Mr. John Day. Midwifery—prize: Mr. Arthur Smith. Forensic medicine—prize: Mr. Bousfield; certificate: Mr. Roberts. Botany—prize: Mr. Clapham; certificate: Mr. A. Smith. A theological prize, the gift of the Rev. D. Laing, the chaplain, was gained by Mr. Boyers. At the conclusion of the meeting a vote of thanks was moved to the chairman; and it was proposed by Dr. Merriman, and resolved, that the thanks of the governors were due to the lecturers for their endeavours during the past session to uphold the character and advance the prosperity of the school.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—*Distribution of Prizes, Session* 1845-46, *Monday, April 27th*—Sir Benjamin Brodie, Bart., in the Chair.—Clinical Medicine: Prize, Mr. Wm. J. Anderson; Honorary Certificate, Mr. Henry Landon. Clinical Surgery: Prize, Mr. Henry Gray. Practice of Physic: Prize, Mr. E. B. Batten; Honorary Certificate, Mr. T. I'anson. Surgery: Prize, Mr. Henry Gray. Materia Medica: Prize, Mr. A. Howse; Honorary Certificate, Mr. G. F. Trimnell. Anatomy: Senior Prize, Mr. James Holloway; Honorary Certificate, Mr. J. H. B. Sandon; Junior Prize, Mr. Robert Hicks; Honorary Certificates, Mr. A. Howse and Mr. Joseph G. Symes. Midwifery: 1st Prize, Mr John Lloyd; 2nd Prize, Mr. H. B. Holl. Botany: Prizes, Mr. Louis Parnell and Mr. W. P. Roberts, equal; Honorary Certificate, Mr. G. F. Trimnell.

KING'S COLLEGE, LONDON. — *Distribution of Prizes—Medical Department.*— Scholarships. Senior Scholarship, William Brinton; John Reid, *proxime accessit.* 2nd Year Scholarship, Samuel J. Augustus Salter. 1st Year Scholarship, George Robert Cubitt, John Cox Lynch, and Charles W. D. Williams. Prizes: 1st Division, 1, William Brinton, 2, John Thomas Arlidge; Henry Stevens (Certificate). 2nd Division, 1, Walter Battershele Gill, 2, John Reid. 3rd Division, 1, J. W. Wilkinson. Anatomy: Charles Thompson; Edgar Malcolm and Wm. Henry Cook, Certificates. Materia Medica: Duncan Ferguson. Chemistry: Henry B. Johnson, Certificate. Botany: John T. Arlidge, S. J. A. Salter, and Charles Thompson, Eql. Certificates. Forensic Medicine: Henry Turner Lane Rooke and John Reid; Thomas Bridgewater and John Farmer, Certificates. Comparative Anatomy: Thomas Bridgewater. Medical Societies' Prizes: 1st Prize, Henry Salter; 2nd Prize, John Thomas Arlidge; Certificate, John Reid.

WAR OFFICE, April 28.—92nd Foot: Assist.-surg. Henry Downes, M.D., from the Staff, to be assistant-surgeon, vice Millingen, appointed to the Staff, 73rd Foot; Staff Surgeon of the Second Class Neil Stewart Campbell, to be surgeon, vice M'Bean, appointed to the Staff. Hospital Staff: Surg. James Archibald Duncan M'Bean, from the 73rd Foot, to be staff surgeon of the second class, vice Campbell, appointed to the 73rd Foot. Assist.-surg. John Crespigny Millingen, from the 92nd Foot, to be assistant-surgeon to the Forces, vice Downes, appointed to the 92nd Foot.

OFFICE OF ORDNANCE, April 27.—Ordnance Medical Department: Temporary Assist.-surg. Edward Schaw Protheroe to be assistant-surgeon.

ROYAL COLLEGE OF SURGEONS.—At the last meeting of the Court of Examiners, the following gentlemen were admitted members of this college, viz.:—Messrs. R. Cockburn; B. Miller; W. Davenport; W. J. Collins; J. C. Clindon; G. A. Knott; E. J. Barken; D. E. Hamilton; H. Smith; J. Mullhanny; S. Clevasse. At the same meeting Mr. William Bennett Dalby passed his examination for naval assistant.

The Annual Distribution of Prizes at University College took place on Thursday, April 30, at two o'clock, the Right Honourable Sir Edward Ryan, Bart, in the chair, when the following honours were awarded.—Prize of £40 for general proficiency to Mr. James Hakes, of London. Medicine—gold medal: Mr. J. T. Clover, of Aylesham, Norfolk; first silver medal: Mr. F. C. Webb, of Stonehouse, Devon; second silver medal: Mr. S. F. Slatham, of Crawford, Middlesex. Botany—gold medal: Mr. William Cock, of Rance, Cornwall; silver medal: Mr. F. C. Webb. Anatomy and physiology—gold medal: Mr. Alfred Williams, of Scarborough; first silver medal: Mr. Thomas Park, of Lincoln; second silver medal: Mr. Joseph T. Clover. Chemistry—gold medal: Mr. Thomas Park; first silver medal: Bholanett Bose, of Calcutta; second silver medal: Mr. B. Davies, of Caermarthenshire. Prize essay—gold medal: Mr. William Bowler, of Tottenham. Anatomy—gold medal: Mr. W. D. Wilkes, of Salisbury; first silver medal: Mr. A. Williams; second silver medal: Mr. Joseph T. Clover; junior class, silver medal: Mr. Joseph Lawrence, of Bath. Comparative anatomy—gold medal; Soorjo Coomar Chuckerbutty of Calcutta. Materia medica—gold medal: Mr. J. W. Blyth, of Abergavenny; first silver medal: Rholanoth Bose; second silver medal: Mr. J. Lawrence. Medical jurisprudence—prize: Mr. John E. Wood, of Rochdale. Midwifery—gold medal: Mr. Thomas Park; first silver medal: Mr. M. J. Booth, of Rockdale; second silver medal: Mr. E. J. Barker, of Loughton. Pathological anatomy—gold medal: Mr. T. A. Cammack. Surgery—gold medal: Mr. John E. Wood; first silver medal: Mr. William Cock; second silver medal: Mr. J. T. Clover. Dental surgery—Mr. Richard de Champ Ball, of Plymouth. Fellows' clinical gold medals—winter Term, 1844: Mr. W. H. Allchin, M.B.; summer term, 1845: Mr. C. H. F. Routh, M.B.

OBITUARY.—On the 23d inst., at 33, West-street Brighton, Harry Blaker, Esq., surgeon, aged 61. On the 25th inst., at Daventry, John Lee, Esq., M.D., aged 44. Died, April 14th, at Carlisle, aged 77, Sir Samuel Heward, F.R.C.S. April 22nd, aged 45, William Eccles, Esq., Recently, of diseased heart and lungs, Thomas Firth, Esq., M.D., M.R.C.S., L.A., &c.

PROFESSIONAL MUNIFICENCE.—The late Sir Simon Heward, Knt., of Carlisle, a Fellow of the Royal College of Surgeons of England, has bequeathed the sum of one thousand pounds in aid of the funds of two hospitals, viz., £500 to the Cumberland Infirmary, and £500 to the hospital in the Abbey-yard, Westminster.

The late Major General Sir Robert Dick, the distinguished hero killed at the battle of Sobraon, was the son of Dr. Dick, a *general practitioner*, afterwards examining physician to the Hon. East India Company. Sir H. G. Smith, who commanded the right wing in the same engagement at Sobraon, is also the son of a member of a general practitioner, his father, Mr. John Smith, having practised many years at Whittlesea, Cambridgeshire.

The prohibition of all clinical teaching at the Paris hospitals, except by the medical officer attached to these institutions, has produced a strong feeling of dissatisfaction among our French neighbours.

A writer in the *Gazette des Hopitaux* insists that the Electric Girl is the victim of chorea, in a somewhat aggravated form, and that the existence of this malady explains the phenomena which have incontestibly been observed in her case.

Dr. Douillet, of Paris, has invented an instrument which seizing a stone in the bladder, so covers it as to allow of powerful reagents, which he affirms will dissolve any kind of calculus, and without any possibility of the touching the lining of that viscus.

FOREIGN BODY IN THE TRACHEA.—The case of a lady has been published, in whom a piece of cotton wool passed into the trachea from a carious tooth. A medical man was called in, and precipitately ran out for another surgeon to perform tracheotomy. In the interval, the husband believing that his wife was at the point of death, inverted her body; the foreign substance was expelled, and before the return of the doctors she was perfectly restored. It should not be forgotten, however, that the foreign substance in falling from the trachea might fix itself in the glottis and cause almost instant death, so that the inversion of the body cannot be considered a safe measure unless the surgeon is at hand with his scalpel.

MORTALITY TABLE,

For the week ending April 25, 1846

Causes of Death	Total.	Average of 5 summers	Average of 5 years
ALL CAUSES . . .	850	892	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	149	162	188

No. 345. **SUMMARY.** MAY 9.

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

(From our own Correspondent.)

ACADEMY OF SCIENCES.

Meeting of the 27th April, 1846; M. Mathieu in the Chair.

Ergotine in External Hemorrhage.—M. Bonjean, an apothecary of Chambéry, forwarded to the Academy the dissected carotids of a sheep; both were divided in August and October, 1845, and hemorrhage was arrested by the external application of ergotine to the wounds. The animal was killed on the 19th of April, 1846, and the section of the vessels was healed without obliteration.

Lithotrity.—M. Leroy d'Etiolles read a paper containing the description of an entirely new system of lithotrity; by this new plan the stone is ground to powder in a few minutes by the oscillatory movements of an instrument, from the central axis of which project in every direction a number of blades and files. This pulverisation will be chiefly applicable to solitary and voluminous concretions, the common method of fragmentation, followed by immediate extraction, still being, in M. Leroy's opinion, preferable when the calculi are small or numerous. Artificial and immediate extraction of the particles of the crushed stone considerably hastens the cure, and has been already used by the author with advantage in upwards of one hundred cases.

M. Heurteloup read, at the same meeting, a paper referring to the same subject. He also advocates the immediate removal of the pulverised calculus, and asserts that this artificial extraction takes up no more time than the operation of lithotomy. M. Heurteloup brings forward, in support of this modification of lithotrity, the possibility of a portion of stone being lost in the bladder after crushing, and becoming inaccessible to instruments; and, secondly, the chances of vesical catarrh, when expulsion of the fragments is left to nature, and the dangers arising from their stoppage in the course of the urethra.

ACADEMY OF MEDICINE.

Meeting of April 28th, 1846; Dr. Roche in the Chair.

M. C. Broussais read an interesting paper "On the Climate and Diseases of Algeria," of which the following is an abstract:—

The essayist began by remarking that the important question of medical constitutions seemed to have been formerly the object of more attention than of late. This interesting study was rendered extremely difficult in temperate climates by the great frequency of vicissitudes in the condition of the atmosphere, and furnished, on the contrary, far more positive results in those countries in which the changes were sudden and less frequent. In this respect Algeria offered a rich field of observation, and M. Broussais had spent there twelve months for the purpose of investigating the subject. After a few prefatory remarks, the author proceeded to the consideration of the first part of his paper, *the Climate of the province of Algeria, and its influence on man.*

In the first place the author, considering that the hours of nine, a.m., twelve and three, p.m., generally chosen for the purpose of observation, vary but little in temperature, preferred taking thermometric observations at six, a.m., [illegible] and ten, p.m., with the assistance of a self-registering thermometer for the night. The climate of Algiers, and of the cities on the coast, such as Constantine, Tlemcen and Medeah, is mild and healthy; in Algiers no winter can be said to exist, but a rainy season, lasting from December to February. The summer is well marked by a continuance of dry heat, modified and rendered supportable by a refreshing sea breeze, which prevails from ten, a.m., until evening. The maximum of the daily temperature is at eleven o'clock, a.m.—a circumstance explained by the same cause which produces the sea breeze, viz., the rapidity with which the sandy soil and the layers of air in contact with it are heated by the morning sun. The sirocco, the wind from the desert, seldom blows more than a few days every year in Algiers; its passage is usually marked with extraordinary physical and physiological phenomena: the hygrometer falls fifteen or twenty degrees during its prevalence, and sudden deaths frequently occur. It has been very generally asserted that the freshness of the night, contrasting with the oppressive heat of the day, is one of the most important generating causes of disease in Africa. Mr. B. was also impressed with this idea when he visited Algiers, and he found, to his surprise, that, in the evening, no sensation of coolness or damp is experienced, and that, during the nights, the thermometer descends only one or two degrees below the mean temperature of the preceding day. In spring and autumn, however, the nights are cold and damp, although not so much as they are commonly in France. In order to obtain accurate data with relation to the temperature of the country, M. B. was not satisfied with examining the heat in the shade and in the sun. In this respect he has found the greatest possible variations, according as the observation was taken in the sun, in an exposed place, in the shade, or in the sun, but under cover, [illegible], at the same hour, 20 deg. in the first, 35 deg. in the second, and 60 deg. in the third situation. The city of Algiers is placed upon a hill facing the rising sun, and forms the western point of the magnificent bay, which is limited to the east by Cape Matifou. Neither in Algiers nor in its neighbourhood is there a single marsh; behind the city runs, parallel to the sea, a long line of hills, constituting the Sahel, separated from the Atlas by an immense plain, in extent 100 miles by 20, called the Metidja; beyond the Atlas is the desert. The Metidja is often covered with dense fogs; its rivers are variable in their course, and in the abundance of their waters, now forming irresistible torrents, and shortly afterwards streams of no importance; the plain itself is interspersed with dangerous and unhealthy marshes; it is divided by a fine road, leading to Blidah, and in its centre Boufarick is celebrated for its fevers and the unwholesome nature of its atmosphere. Thus Algiers, built in an amphitheatre on the sea, is a salubrious city, protected from the marshy exhalations of the plain by the hills of the Sahel, beyond which extend the fenny and damp plains of the Metidja. Such is the climate of the province; what may be its influence on the constitution of Europeans?

In temperate countries the air is rich in oxygen, the chemical phenomena of life are active, considerable expenditure of the fluids of the body takes place, and the necessity of a reparation and a nourishing diet is energetically felt. In Africa the wants of the system are not so pressing, and yet the amount of food taken by Europeans is as great as it is at home; through fear of weakness, caused by the enervating heat, many have recourse to stimulants. The blood, already too rich for the climate, becomes overloaded with fibrine, and nature generally endeavours to relieve this condition by diarrhœa, which often takes on, if neglected, a dysenteric character. The functions of the skin become for many extremely active, and abundant perspiration gradually weakens the system, particularly if exercise is indulged in to any extent—a circumstance which is looked upon by the natives with mingled feelings of wonder and pity. Hence, three causes of disease from the influence of the climate: from the too fibrinous condition of the blood, a tendency to inflammations; from the too solid nature of the nutriment in general, diarrhœa, and disorder of the digestive organs; and from unnecessary expenditure of nervous action, debility.

Durand de Lunel on Intermittent Fever. Reported by Prof. [illegible].

Dr. Durand has observed intermittent fever at Tenès, in Africa, and has stated a new theory of ague, of which we will endeavour to convey some idea. He begins with an assertion that the body expands during the day, and concentrates its circulating fluids at night; that the heat of the day is a sedative of the ganglionic system of nerves, and a stimulant to the nerves of relation; and that night and cold act in an opposite manner, calming the nerves of sensation and exciting the inner [illegible]. Here would be the real cause of periodicity. The spleen receives the miasma, and, becoming the receptacle of putrid blood, is in fact a sort of internal swamp; under the influence of nocturnal concentration, it retains the fluids, and the daily expansion throwing into the vascular system a large quantity of tainted blood, the febrile manifestation is the result. From a statistical account furnished by the observations of Dr. Maillot, of Bona, Dr. Pinet, of Blidah, and M. Durand himself, it appears that, of 6645 cases of ague, the paroxysm was diurnal in 4576 cases, and nocturnal in 2069. In further confirmation of his singular theory, Dr. Durand states that, having examined in the morning by palpation the hypochondrium of many patients affected with intermittents, he found the spleen protruding considerably below the fa

ribs; in the afternoon, on the contrary, the viscus had receded, and could no longer be felt. Such is Dr Durand's theory, and such the facts on which it is supported. From these very facts, the learned reporter drew conclusions in direct contradiction with those of the essayist. Rejecting the proposed theory as insufficient and erroneous, Professor Piorry pointed out the fallacy of M. D.'s assertion that the paroxysms of fever were caused by the contraction of the congested spleen, by which the putrid blood was forced into the system. Now, if such were really the case, the spleen should be found *smaller* during the paroxysms, and *larger* in apyrexia—a supposition contradicted by percussion. If such was the case, it is clear that the spleen, expanding at night, all febrile paroxysms should take place by day, and yet we are informed by Dr. D. himself that, out of 6645 cases of ague, the paroxysms were nocturnal in 2069 instances. This is a palpable contradiction which would suffice to overturn Dr. Durand's entire theory. But a more important objection still may be raised against it—How has Dr. Durand ascertained the increase of the spleen?—by mere palpation below the false ribs, a method of exploration which can yield only the most erroneous results. The spleen is not fixed in the hypochondrium, but varies considerably in position according to the state of repletion or vacuity of the neighbouring organs, and its precise seat, size, and shape can be correctly appreciated but by one method, viz., plessimetric percussion. By this method the constancy of enlargement of the viscus in intermittent fever is now a demonstrated fact; percussion has even shown that this enlargement may pre-exist to the first invasion of fever, and that repetition of the paroxysms is not the cause of the increase of size, which must be referred to persistency of the marshy influences which first produced it. It has further been proved by percussion that the treatment is not to be directed against the fever, but against the disease of the spleen; and that the size of that viscus is speedily reduced to its normal standard by the exhibition of the soluble salts of quinine, or of quinine dissolved in alcohol. When the fever is caused by marshy emanations, the enlargement of the spleen is constant; but when, on the contrary, the periodic symptoms are referrible to other causes, this is not the case. The opinions of the essayist cannot, therefore, be entertained.

The report was unanimously adopted, and the meeting adjourned at five o'clock.

LA CHARITE.

CLINICAL LECTURE.—*Disease of the Spinal Cord*; By PROFESSOR VELPEAU.

A man, aged nineteen, was admitted into hospital for an abscess situated on the left side of the chest. Another tumour, apparently occupying a lymphatic gland, was observed above the left clavicle. The general appearance of the patient was unfavourable, although the appetite was preserved and sleep undisturbed. He had been under treatment for one month, when he began to lose the use of his legs, complete paralysis of motion setting in rapidly; sensation, however, remained perfect, but the bladder and rectum were also soon affected by the disease. Sloughing of the skin appeared, and the patient gradually sank, but on the day of his death the preservation of sensation was distinctly ascertained all over the body. For some days before the superior extremities were partially paralysed, and considerable anasarca with ascites was present. M. Velpeau had been led to diagnose disease of the anterior portion of the spinal cord, on account of the well-marked preservation of sensation; he was induced likewise to suppose that the dorsal part was the region occupied by the alteration, the exact nature of which he could not specify. The post-mortem examination accounted in a satisfactory and interesting manner for all the symptoms observed in this singular case.—The abscess of the left mamma was found not to correspond with any disease of the ribs. The spinal column was cut open, and from the sixth cervical to the second dorsal vertebra was found a collection of concrete pus, lying between the bodies of the vertebræ and the dura mater, and causing compression of the cord, the substance of which was in a perfectly healthy condition. The vertebræ were carious on their surface, and communicated by a fistular passage with the supraclavicular abscess. The veins of the lower extremities were found obliterated by ancient clots of blood. Paralysis of voluntary motion alone, attended up to the patient's death with preservation of sensation, is in itself a sufficiently remarkable circumstance to fix your attention. The division of the spinal nerves into nerves of sensation and of motion, according to their origin, from the anterior or posterior portions of the spine, has caused of late much discussion and research, and has been generally decided by an appeal to experimental physiology. Pathology has seldom contributed to the solution of the question, and the present case is on that account most valuable. M. Velpeau has already observed an almost similar instance in a woman, who died at the hôpital Des Cliniques some twenty years ago. Paralysis was present, but sensation was preserved; a sort of fungus, of a cancerous nature, was found occupying the *anterior* region of the spinal cord.

CRUSHING OF HEMATIC TUMOURS.—You have observed in the wards a woman who presents on the outer part of the left leg a brownish tumour perforated by an incision in its centre. The tumour was produced by the fall of a heavy body on the limb. The incision was made by a surgeon who was called to the patient before her admission into hospital. This was a useless, and might have become a dangerous operation; when under the influence of any external violence blood is extravasated, it collects, or is diffused in the cellular tissue. In the latter case, absorption rapidly takes place, and no operation is necessary; in the former, the tumour can be removed in nine cases out of ten without resorting to the knife. The hematic collection might disappear by the unaided efforts of nature, but is rapidly cured by the method of *crushing*, by which the collection is changed into a mere infiltration. Indeed we may say that incision is not without its danger, as it may cause inflammation of the hematic tumour and diffused phlegmonous suppuration of the extremity. When, however, the hematic tumour has resisted all the efforts of the surgeon to produce absorption, when inflammation has set in, an incision may be necessary, but never immediately after the production of the accident.

HOTEL DIEU.

CLINICAL LECTURE.—*Intestinal Obstructions*; By PROFESSOR CHOMEL.

A patient recently died in our wards from the presence of intestinal obstruction. She was a woman, aged nineteen, of a strong constitution, and enjoying usually good health. Six months before her death she miscarried, and presented afterwards all the symptoms of peritonitis. It was impossible, on inspection of the preparation, to doubt that the inflammatory symptoms originated on the surface of the womb. It is, gentlemen, a remark we have often had an opportunity of making, that no disease is more rare than primary spontaneous peritonitis; when, therefore, you are called to a case of inflammation of the peritoneum, you should first endeavour to ascertain by what disease it has been produced, and in the detection of this primary malady you will find the most urgent practical indications. Our patient, had therefore, been affected with peritonitis consequent upon inflammation of the uterus after miscarriage. These symptoms had subsided, when about a fortnight before death new pains appeared in the abdomen, attended with frequent, almost continuous, vomiting. When she was admitted into hospital the extremities were cyanosed, the pulse 120. The vomiting continual, and the peristaltic motion of the intestines visible through the abdominal walls. The belly was not meteoric, and the matter vomited, at first of a bilious nature, soon acquired a fæcal odour, and left no doubt of the presence of an obstruction in the course of the intestine. Various purgatives were unsuccessfully exhibited, and the patient lived only forty-eight hours after admission into our wards. On dissection, the omentum was found to adhere at one point to the inner surface of the pelvis, and marks of inflammation were readily detected all over the serous membrane. In the hypogastric region solid adhesions were discovered; the first seven feet of the small intestine were in a state of considerable dilatation, equalling in size the large intestine. The digestive tube was, on the contrary, atrophied from the union of its two superior with its inferior third, and was much narrower than in health. In the exact spot where the exaggerated dilatation of the intestine ceased, the ileum was strictured by a portion of intestine lying across it, and firmly attached by one of its extremities to the brim of the pelvis, and by the other to the omentum. The occlusion occupied the left side, and above it the small intestine was half twisted on its axis. In several other parts of the pelvis peritoneal adhesions seemed also to interfere more or less with circulation of matter in the cavity of the digestive organs, the lower parts of which contained neither gas nor stercora; above the stricture was accumulated a large quantity of liquids. We found also an ulceration of the rectum, which does not seem to have any connection with the causes of death; the womb was healthy.

The disease of which this unfortunate woman presented an example has been but imperfectly studied. The names of ileus, volvulus, meserere, iliac passion, &c., have been generally employed to designate it. In the description of a disease it is not our custom to begin with the anatomical alterations; it appears to us more rational to investigate first the causes, symptoms, progress, and treatment of a disease, before entering upon the examination of the physical changes it has produced; but, in the description of some maladies, we are forcibly obliged to modify this general rule, because the anatomical alteration is the chief point—the important feature, without a correct knowledge of which no insight into the nature of the disease can possibly be obtained.

Morbid Anatomy.—The anatomical cause of obstruction will be found occasionally to reside in the intestinal cavity, in the walls of the digestive tube, or in some neighbouring organs. Thus we find that strangulation may be caused by epiploic adhesions situated in any part of the abdominal cavity. The appendices of the omentum, the appendix vermiformis, occasionally incarcerate a portion of intestine, and we have seen in the melancholy case which we related at the beginning of this lecture, that an intestinal convolution may press like a ring against another part of the tube, and obliterate its cavity. It is not impossible that strangulation of a portion of intestine may take place through a laceration of the diaphragm, and lacerations of the omentum or mesentery have been observed to give passage to and to strangulate a convolution of the ileum or jejunum. Another form of intestinal obstruction, *intussusception*, is not unfrequently observed; not that intussusception is always followed by fatal symptoms. A portion of the small intestine may accidentally be invaginated in the neighbouring part of the digestive canal without the production of any severe accident, particularly in children. You will often find in them intussusception to be merely a cadaveric alteration, or to have been produced during the last moments of life. But the most dangerous of all forms of intussusception is undoubtedly the reception of the small into the large intestine. The immobility of the colon, and the presence of the ileo-cœcal valve, render constriction inevitable, and its consequences more dangerous. We should also say that if this is the severest, it is also the least frequent form of invagination. The obstacle once established, fæcal matter cannot pass onwards; the venous circulation of the part is arrested, and symptoms of inflammation appear. The intestine may also be completely twisted round, so as to be completely impervious in one spot. This is an uncommon sort of obstruction; but has been observed in several instances, and in one case in particular, related by M. Andral, the entire mass of the small intestine was twisted by a universal movement of rotation, so as to present an insurmountable obstacle to the progress of its contents.

DAN. M'CARTHY, D.M.P.

UNIVERSITY OF EDINBURGH.—Mr. John Goodsir, the well-known anatomist and microscopist, has been elected the Professor of Anatomy in this university. He was long the pupil and assistant of a distinguished contributor to our pages, Dr. Knox.

ANATOMICO-PATHOLOGICAL OBSERVATIONS UPON PHTHISIS.

By D. José Seco Baldor.

(Continued from page 52.)

Case 5.—*Acute Pleurisy assuming the Chronic Form; Empyema; Sub-cutaneous Abscess; Evacuation of both by Incision. Tubercles in the Pseudo-membranes and in both Lungs; Ascent of the Liver to the Superior Part of the Sixth Rib.*

A young soldier, of dark complexion, and well-constituted, came, in the beginning of April, 1837, into the Military Hospital of Saint-Isabel. From his own report, he had, two months previously, in consequence of having drunk very cold water, been seized with an acute pain in the inferior third of the right side of the chest between the anterior and lateral part, followed by other symptoms of pleurisy. He had never before suffered from any thoracic affection. On the morning of the 30th, six days after his admission, he exhibited, upon examination, the following appearances:—Face and whole surface of the body, pallid; cheeks flushed; incipient marasmus; considerable debility; hot skin; pulse frequent, small and weak; access of fever, with perspiration, in the evening and during the night; thirst excessive; appetite bad; dyspnœa; cough not very frequent; free expectoration of thick, ash-grey, homogeneous mucus which adhered to the spitting-pot reclination dorsal. In the situation, in which the pain first presented itself, a tumour, evidently formed by an abscess, augmenting with the cough, diminishing on compression; and, in both cases, exhibiting an evident fluctuation. Sound (on percussion) clear in the whole of the left side, and in the two superior thirds of the right anterior and lateral regions; obtuse in the inferior third of these regions, and in the whole posterior part: respiratory murmur very evident in the whole left side, in the anterior part of the right, to the distance of two fingers' breadth below the nipple, and in the corresponding axilla: obscure, with mucous *râle*, in the posterior part; less obscure, and with diminished *râle* in the middle third of the lateral region: extinct, without *râle*, in the inferior third, and the anterior, of this region: in the right posterior region, a peculiar sound of the voice,—imperfect œgophony,—not perceptible in the left. Diet broth and milk Pectoral decoction: opiate pills.

On May 1st, a considerable quantity of pus was discharged, by incision, from the abscess: it was wholly phlegmonous, and without smell, and at last frothy There was no evening accession of fever, and the dyspnœa was relieved.

2.—Purulent discharge thick; cheeks less flushed. Dyspnœa, as on the preceding day. Recurrence of the fever

From the 3rd to 8th, the pus, which issued from the aperture in the abscess, was clear, and small in quantity; the expectorated matter clear and very scanty; perspiration slight, and urine abundant. The patient took a nitrated demulcent decoction, alternately with the pectoral.

18.—Percussion and auscultation afforded the same results as previously to the opening of the abscess. The only difference was that the voice resounded equally in both sides, and that, in the anterior part of the right, there was sonorous *râle*. In other respects, no alteration.

9.—A cautery, of pure potass, applied to the right posterior side of the chest; and, on the 10th, another three fingers' breath above the first. During these days, the cough was less frequent; and no expectoration. Asses-milk, in a morning.

16.—A transparent serous pus continued to escape from the abscess. The dyspnœa was slight, and scarcely felt by the patient; cough, of rare occurrence; expectoration scanty; reclination equally commodious in every posture; fever much diminished; perspiration gone; bowels spontaneously moved; appetite and thirst regular; urine abundant; countenance improved; mind of the patient tranquil and cheerful. Asses-milk continued, with the pectoral and nitrated decoctions. Another cautery in the anterior right part. Goat's-milk, with an allowance of bread, and soup.

19.—A relapse; and the bread consequently withdrawn From this period, the patient grew daily worse, and died on July 21st. During this period, the fever returned every evening, and, generally, in a morning. Within the last few weeks, the debility and marasmus were rapidly aggravated by the supervention of diarrhœa. Percussion and auscultation invariably yielded the same results as previously to the 19th of May; except that the sound was dull, and respiration obscure, or quite extinct, in both sides, posteriorly. The dyspnœa was somewhat aggravated, but never extreme. The opening in the abscess became fistulous. Towards the close of life, the patient lost his appetite which had previously been good; and there was œdema of the lower extremities, commencing in the right limb.

NECROTOMY ON THE MORNING OF THE 22ND.

The right lung adherent, by all its surfaces, to the contiguous parts. False membranes attached posteriorly and to its internal surface, thick, firm, white, and, in fact, fibrous. From the superior part of the internal surface of the sixth rib to the second, passed obliquely a thick, firm, pseudo-membranous septum, which thrust the lung backwards, and kept it suspended in the superior half of the thorax. The liver rose to the point at which the lung terminated,—the superior part of the sixth rib. The left lung free in the pleuritic cavity which contained some ounces of transparent serum. Both lungs tuberculated, especially in the posterior part, which was hepatised. In the right, a few caverns, and many more tubercles than in the left. Some white small tubercles (tuberculitos) in the false membranes. Heart small, pale, and flaccid.

REFLECTIONS.

Here is another conspicuous instance of the ascent of the liver, consequent on removal of the pus which had been poured out into the right pleura. In the two former cases, the fluid had been absorbed; in the present, discharged by an effort of nature seconded by art. When it was discovered that the sub-cutaneous abscess communicated with the empyema, and that great relief succeeded their evacuation, some hopes of recovery were entertained. But inflammation of the pleura went forward: the lungs,—especially the right,—in their posterior part, were involved in the same process; and death took place; although more slowly than if the pus contained in the pleura, had not been evacuated.

The existence of the tubercles was not indicated. The empyema, the inflammation of the lungs, and ascent of the liver rendered the diagnosis obscure; and the caverns, being small and few, were discoverable neither by auscultation, nor by inspection of the expectorated fluid. The perspirations which, in chronic diseases of the chest, almost invariably coincide with the existence of pulmonary tubercles, were not, here, attributable to this lesion, but to the suppuration of the pleura and of the subcutaneous tissues adjacent to it: since they diminished, and even ceased entirely, after the evacuation of the pus.

At all events, the tuberculization, in this case, was, doubtless, consecutive to the pleurisy, and the effect of it. This fact is clearly demonstrated by the robust constitution of the patient, the integrity of the thoracic organs and their functions, previously to the pleuritis, the existence of tubercles in the pseudo-membranes, the site which they principally occupied in the lungs, and, lastly, by their greater number, and more advanced condition, in the right than in the left lung.

Nor, considered in its relation to semeiotics, is this case deficient in interest. Whilst a certain quantity of pus had been effused into the right pleura, imperfect œgophony was perceptible. When the greater part of the fluid had escaped, this phenomenon ceased; and the voice resounded equally in both sides of the thorax. Œgophony does not occur when hepatization of a great part of the lung coincides with the existence of a certain quantity of fluid in the pleura; as happened in, some of the preceding cases. In the present instance, as the hepatization of the right lung was not very extensive, and as, moreover, this morbid change occurred posteriorly to the purulent collection, there was no obstacle to the existence of the œgophony.

Case 6.—*Pleurisy, Gastritis: some Tubercles in the Lung corresponding to the Inflamed Pleura.*

A dark-complexioned, bilious, muscular soldier the son of robust parents, had been, for a long time, first in the hospital of Lavapies, and, afterwards, in that of St. Isabel His symptoms were epigastric pains, loss of appetite, thirst, disagreeable taste in the mouth. The tongue was constantly inflamed on the margins, and foul in the centre. Dyspepsia, eructations, vomiting, constipation of the bowels, pallid and yellow countenance in short, all the unequivocal characters of chronic gastritis. At first, there was no fever; afterwards, an evening-paroxysm. He lay invariably on the right side, yet neither the posture, the evening-fever, nor the progressive loss of strength and flesh, engendered any suspicion of the existence of thoracic disease. The peculiarity of reclination was regarded as the effect of habit, and the other symptoms as wholly dependent on the progress of chronic gastritis.

August 6, 1836.—The patient was observed to respire with difficulty, and cough He then stated that he had occasionally felt transient pains in the right side of the chest, particularly in the shoulder-blade; that he reclined on that side because he found his respiration worse when lying on his left, and that his cough, constantly dry, had existed, more or less, for eight days. The left side of the thorax emitted, everywhere, a natural sound, and the respiratory murmur was clearly perceptible. In the superior half of the right side, it was clear; in the inferior, obscure, or perfectly extinct. The sound, on percussion, also, was more or less obtuse; and, in this side, there was manifest œgophony, especially in the posterior part.

With such symptoms it was impossible to doubt the existence of chronic pleurisy of the right side; which contributed more than the gastritis to the production of the evening-fever. To the plan of treatment already employed, was added the institution of a caustic issue in the diseased side of the thorax, but without effect. The fever continued with severe evening and night-exacerbations; during which the dyspnœa was aggravated; the cough frequent, and heat of the skin intense, followed by profuse perspirations over the upper half of the body. The debility and emaciation increased; the respiration became puerile in the left, and extinct in the whole of the right side, except near the track of the vertebral column. The œgophony disappeared; and the sound became obtuse over the whole of this side. The patient sank exhausted, on August 26th.

NECROTOMY A FEW HOURS AFTER DEATH.

Abdomen.—The whole gastric mucous membrane, of a deep-red colour, and, in some points, so much softened, that on slight scraping with the scalpel, it separated from the muscular coat, as though it had been a pulp applied to that membrane. The duodenum, in parts, somewhat red The remaining portions of the intestine healthy The whole digestive tube meteorized, especially the stomach and duodenum. Some transparent serum, without vestiges of inflammation, in the peritoneum. The liver projected two finger's breadth below the margin of the ribs. Other abdominal viscera sound.

Thorax.—Adhesion of the right lung to the contiguous parts. Between the pulmonary, costal, and diaphragmatic pleura, divers pseudo-membranous cells, containing a great quantity of gelatiniform serum; which, while compressing the lung against the vertebral column and the heart, thrust the liver downwards, and caused it to project below the margin of the ribs. The pulmonary parenchyma neither indurated, softened, nor affected with hyperæmia. The only lesion which it exhibited was *some minute tubercles*, congregated in a small space, near the surface. The left lung was perfectly sound, and pervious to the air; but small in volume At least, there existed a considerable space between it and the ribs. The bronchial mucous membrane, pale and healthy.

REFLECTIONS

The principal interest of this case consists in its incontestibly demonstrating that the tubercles, developed in the right lung, were not of constitutional origin, since the subject exhibited no sign of tubercular predisposition; and that they did not induce the pleuritis; as they were too few in number, and occupied too small a space, to excite inflammation and suppuration of the whole membrane. Neither could they be regarded either as cause, or effect, of a bronchitis which was not an

nounced in the living, nor met with in the dead body. They were in fact, excited by the pleurisy, and posterior, in date, to the empyema. This was clearly indicated by their nascent condition their limited number, and the situation which they occupied, in the vicinity of the pulmonary pleura, inflamed as all the other portions of the right pleura were.

Laennec, if he had witnessed this dissection, would have been driven to extremity in proving the priority of the tubercle. Few cases could occur, so well calculated as this is to subvert his opinion, and establish the correctness of the views of Broussais and other writers, who concede to pleurisy the power of occasioning the development of tubercles in the lungs provided there exists a corresponding predisposition, innate or accidental (in the patient's system) for without this, such development is impossible. The predisposition, in this subject, was accidental, and produced by a deteriorated state of the blood and of nutrition as happens in other cases in which the tubercular diathesis manifests itself when, in consequence of some chronic malady, the blood has become vitiated, and the patient exhibits as the ancients termed it, a cacochymic and ill-conditioned appearance. The individual constitution under these circumstances, becomes identified with, or resembles, that of persons possessing an innate predisposition to the development of tubercles.

Percussion and auscultation were, here, very useful as instruments of diagnosis since they not only detected the inflammation of the pleura but indicated, with great precision, the progress of the empyema.

The obscurity in which the origin and progress of this pleurisy were involved, presents nothing remarkable. Frequently, during the course of a chronic disease, others become developed, which have not been suspected to exist in the living, and are discovered with surprise, in the dead subject. Nevertheless, had this man communicated the fact of the occurrence of the lancinating pains in his chest, and the inconvenience resulting from reclination on the left side, the pleurisy might have been detected by percussion and auscultation, previously to its discovery from the cough and dyspnoea. In military hospitals, if the physician do not take the trouble of examining, daily and with great attention, all his patients, many of them will pass days, and even weeks, without communicating to him any new ailments particularly when they apprehend that a reduction in the allowance of food may be the consequence of such communication. It is impossible to say whether, under any circumstances, this patient would have recovered but had the author's attention been directed, at an earlier period to the state of the thoracic organs, so much valuable time would assuredly not have elapsed without a strenuous effort to resist the invasion, and check the insidious progress, of the pleurisy.

It may be remarked that the parenchyma of both lungs was untouched, with the exception of the few incipient tubercles developed in the right, and that the bronchial mucous membrane was, moreover, perfectly sound. These circumstances explain the tardy occurrence of the cough, and its dry character to the close of life. Here, also, is an instance of the [illegible] of the liver, as shewn in case 4.

With regard to the inflammation of the stomach, it not only occupied the whole mucous membrane which was, in part, manifestly softened, but had propagated itself to the duodenum although in the intestine simple hyperæmia, only was observed.

(To be continued.)

England.

OVARIAN DISEASE.—Mr Middleton, in the *Provincial Medical Journal* describes the case of a patient of his who was affected with ovarian disease and who sunk exhausted fifty-three days after he had practised paracentesis abdominis. The body was inspected twenty-six hours after death. Upon opening the abdomen, about a pint of clear ascitic serum, escaped from the peritoneal cavity. After separating by the hand the probably recent peritoneal adhesions existing between the abdominal parietes and the anterior aspect of the tumour, a large irregularly distended bag became exposed, of a strong fibrous texture, having an uneven surface, and apparently subdivided into several compartments containing fluid, while more or less connected with solid matter above and anteriorly. A small quantity of fluid lymph was visible in a slight depression on its surface. After getting through the omentum, which was extended over, and firmly adherent to, its upper surface, it was found intimately connected posteriorly with most of the contiguous structures, by numerous thick layers of a strong membranous character, consolidated together into one mass, which was exceedingly difficult to overcome, and its detachment and removal could not be effected without much rough work with the knife, and the escape of the contents of several large cysts, containing many pints of fluid of a sero-purulent character, which displayed, by the consequent collapse of a portion of the structure, the mixed nature of this anomalous development. The bladder at its upper part was firmly fixed to it, while the uterus was entirely unconnected, being perfectly distinct, although smaller than natural, and having internally merely lost the triangular character peculiar to its healthy condition. The left broad ligament was obliterated by its extension over this large collection of disease, seemingly constituted by the enormously increased left ovarium, with its tube imbedded in it. The right ovary was small, but healthy, and the tube of this side was extended adherently upon the under surface of the tumour the cul de sac, between the vagina and rectum, was curiously lined by a dark bluish membranous exudation, detached with little difficulty, probably from the congested capillary hæmorrhoidal veins. The stomach and bowels were much attenuated from long inanition, the latter also extensively matted together by adhesive inflammation. After pressing out from some of the cysts a large quantity of sero-purulent fluid, containing numerous little flakes and masses of a curdy consistence, the examination of the structure after removal, more clearly demonstrated its heterogeneous nature. It contained numerous large cysts, which upon opening were found to contain others, successively diminishing to three or four deep. They were distinct, and distended with serum, in which floated, in many instances, long streaks of a soft gelatinous substance, many smaller conglomerated together, confining a yellowish serum, and on the lower right side a small nest of true hydatids was attached, about the size of grapes. The interior of this structure seemed to some extent broken up by the ulcerative process, which had destroyed the cystic arrangement, and no doubt poured out a sufficient quantity of pus, which, by being blended with the proper cystic secretion, had given character to the bulk of the fluid. This altogether amounted to twenty-four pints. The solid portion, situated at its upper and anterior aspect, was chiefly of firm consistence, and more or less elastic, it had a smooth surface, and was of a light liver colour, while several parts, inclining more internally and more immediately in contact with the cysts, were of a looser and more spongy character. Dividing it with a knife displayed its fibrous texture, and afforded in many of its parts so many excellent illustrations of encephaloid disease. In others ulceration had made considerable progress, partly reducing the structure, and having it of a distinctly cellular character, exemplifying another interesting form of disease, the honeycomb structure. In several different portions, when dividing the solid matter, occasionally would appear an isolated hydatid, about the size of a small walnut. The weight of the solid matter was altogether thirteen pounds. It is certain ovariotomy could not have been practised in this case, on account of the numerous and important adhesions the diseased ovary had contracted with the neighbouring organs.

CROTON OIL IN DELIRIUM TREMENS.—Mr Prankerd has published, in the *Provincial Medical Journal*, a communication on the employment of croton oil in delirium tremens. He says, in the treatment of this disease, to procure sleep, and thus prevent the continuance of the delirium, is the great object to be attained, and opium would at first appear the remedy most appropriate to fulfil this indication, but his experience leads to a different conclusion. As far as it extends, opium has entirely failed, or, where sleep has been induced, the patient has awakened with many of the symptoms aggravated. In the *Dublin Journal of Medical Science*, January, 1841, Dr Ware, of Boston, United States, published a statistical account of sixty-nine cases of delirium tremens, of eight patients who were treated by large doses of opium, four died, of seven treated by small doses, two died; thus giving six deaths out of fifteen cases, in which opium was the principal remedy employed, whilst in the remaining fifty-four, in which opium was not used, or only incidentally in small quantities, only five died. This difference in the results of treatment Dr Ware considers too great to be attributed to accident, and to go far to establish the truth of the opinion that opium, in large doses, is actually injurious to patients labouring under delirium tremens. The acknowledged benefit derived from the administration of croton oil in certain nervous diseases, attended by a high degree of excitement, such as hysteria, epilepsy, neuralgia, &c., combined with the failure of opium in those cases of delirium tremens which have fallen under Mr. Prankerd's care, first induced him to give this medicine a trial in this formidable disease, and the success he experienced has been such as to lead him to publish the result, the more especially as, although he has frequently met with complaints of the insufficiency of the usual mode of treatment, he has not seen any detailed account of cases in which this remedy has been employed. Five cases of delirium tremens are recorded by him, in the first two opium alone was relied on, and both patients died, the first took six grains of morphia and five grains of opium, equal in all to seventeen grains of opium (allowing one grain of morphia to be equal to two of opium), in less than twenty four hours, without procuring sleep, and the other took fifty seven grains of opium and twelve of morphia (equal to eighty-one of opium) in six days, besides using morphia endermically, with camphor, ammonia, and various stimuli, internally. The third patient took thirty-six grains of solid opium, one grain and a half of morphia, and a drachm of Battley's solution, in four days, the disease continuing to get worse, when Mr Prankerd prescribed the croton oil as follows:—℞ Ol. tiglii, ♏ viij., Mist. acaciæ, ℥j., Syr. rhœad., ℥ss; Aquæ puræ, ℥iv. M. Capt. coch. larg. ij omni horâ. After the patient had taken eight doses of this medicine, he was very freely purged. The excitement gradually lessened, and he had refreshing sleep for several hours. Alteratives and gentle aperients were afterwards used for a few days, and he perfectly recovered. He afterwards experienced a second attack, and Mr Prankerd not being then fully satisfied as to the effects of the croton oil, had recourse to opium in large doses, giving it in various forms, equal in amount to 169 grains of the drug in the course of six days, but without permanent benefit. On the seventh day he began with croton oil, giving a drop every half hour, after eighteen doses had been taken, which had a most powerful effect on the bowels, the patient had refreshing sleep, and all the symptoms were relieved. A little stomachic medicine only was afterwards required. In the fifth case, one of delirium tremens complicating a fractured and ulcerated leg, ten drops of croton oil were given in seven hours, and two drops a few hours after. The relief was most decided, and the patient got well. In some remarks on these cases, Mr Prankerd observes that they will, he thinks, justify him in concluding that the administration of croton oil is attended with decided benefit in cases of delirium tremens—a disease complicated generally with other affections, chiefly those of the liver and stomach, the depraved secretions of which may in many instances, keep up the irritation. But to the removal of these he does not attribute the favourable result, but rather to the croton oil acting as a direct sedative to the nervous system. He considers it of minor importance how sleep was procured, so that it was of sufficient duration to produce a permanent effect on the disease, and the benefit occurring in these cases has been so marked as henceforth to give him a decided preference for its administration. The quantity given in so short a time would appear almost incredible, but as he had often given a drop every quarter of an hour in epilepsy to the extent of twelve or fourteen drops, he felt justified in continuing the

emedy until the effect sought for occurred; and in no instance has he observed any bad effect follow its administration It will be seen that opium had a fair trial At one time he gave it in moderate doses, gradually increasing, at another a full dose, followed by smaller at short intervals, at another continued large doses. He used the solid opium, and various preparations—laudanum, black drop, Battley's solution, and morphia—and in neither of the cases did he observe any decided benefit; sleep was often procured, but never sufficiently to renovate the nervous system.

GALVANISM IN UTERINE HÆMORRHAGE.—Mr. Wilson, in the *Provincial Medical and Surgical Journal*, describes a case of severe uterine hæmorrhage, occurring in a woman, thirty-four years of age, about two months advanced in pregnancy, and which had been going on for about a week before he saw her In spite of the internal exhibition of gallic acid and ergot of rye, the use of the tampon and vaginal and rectal cold water injections, the hemorrhage continued, and at last the case appeared to be utterly hopeless. The patient could no longer swallow the brandy, and was only roused from a state of apparent insensibility, bordering on syncope, by the scarcely interrupted application of ammonia to the nares The pulse had almost forsaken the wrist, being doubtfully perceptible, the eyes remained rigidly open, and fixed; in short, death seemed imminent As a *dernier* resort, with but faint hopes of doing any good, Mr. Wilson resolved to try galvanism, as suggested by Dr. Radford. A copper wire, coated with thread and sealing wax, with a ball of moistened sponge, about the size of a nut fastened to one end of it, served for a vaginal conductor The sponge was passed within the os uteri and there retained. The conductor from the other pole of the apparatus was then applied over various points of the sacrum and loins, and shocks and continuous currents of the galvanic fluid transmitted through the parts intervening between these points and the sponge at the os uteri Ten minutes elapsed ere the patient appeared sensible of the galvanic agency The first indication of this was observed in her countenance, her glassy, corpse-like eye, brightened up with something of its wonted expression In the course of ten minutes more the pulse was more distinctly perceptible, and she complained of pain in the abdomen After continuing the galvanic influence for a few minutes longer the apparatus was withdrawn A decided improvement soon followed, and although she suffered for some little time from the effects of excessive loss of blood, under judicious treatment her recovery has been progressive and satisfactory.

[The following are the only articles of interest to the profession in the last three numbers of the *Lancet*.]

THE ALKALOIDS.—The Messrs Smith contend that there can be no real difference in the action on the human economy of the acetate, muriate, and sulphate of morphia, and they consider that the reasons which should lead to giving a preference to any one salt of an alkaloid are the following:—Which is the most readily and easily prepared? which is most readily got in a state of purity, and sufficiently soluble? and which is least liable to change or decomposition? Taking these characters for guides, in the case of the morphia salts, the muriate ought decidedly to have the preference. In the case of the quinine salts, the sulphate should be preferred, for on account of its sparing solubility on crystallising, the greater part of the impurities are left behind in the abundant mother liquid It has also occurred to them, that it might be advantageous to medical men to suggest, that in administering externally some of the alkaloids, such as aconitina and veratria, in the form of ointment, the activity of the remedy would be more [illegible] secured by dissolving them in a few drops of a weak acid, such as the acetic, before mixing them with the ointment In this way their [illegible] more effectually secured, and disappointment in the result less likely to happen.

HYDATIDS OF THE UTERUS DURING PREGNANCY.—Mr Yeates Hunter describes a case of parturition to which he was called, and on examination per vaginam, he found the os uteri dilated, and the head presenting; but the presentation was by no means distinct, and was ascertained with some difficulty, because a soft pulpy mass (evidently not the placenta) intervened between the presenting part and the finger. After a few pains the membranes ruptured, at which time he heard a very peculiar crackling noise, and on again examining the patient, the infant's head had passed below the pulpy mass, which was then beyond his reach The labour progressed very favourably, and the child, which was small, was born in less than two hours after his arrival. After waiting some time, it became necessary to remove the placenta. When the hand was introduced for the purpose, the uterus was found distended by what afterwards proved to be hydatids, measuring about three pints. They were in clusters, like bunches of grapes, some of them being the size of hot-house grapes, but others, and by far the greater number, of the size only of the common blue cluster grape When the placenta was detached, it was found to be lobulated, and of an average size, the hydatids appeared to have been attached to a part of its margin, as well as to the uterus. The patient is doing well Mr. Hunter remarks that he never before saw or heard of a case in which hydatids of the uterus were found in the pregnant organ, and that his medical friends consider the case to be unique and interesting We can assure him that although certainly interesting, it is by no means unique. We had about a year ago under our own care a case of hydatids of the uterus, which were spontaneously discharged after the termination of labour, and other cases of a similar nature have been placed on record.

INFANTILE BRONCHITIS.—Mr Thomson thus states his plan of treating bronchitis in very young infants. If the child be but newly seized, and a good deal "stuffed at the chest," the pulse and breathing very frequent, and the heat of surface much increased, he gives calomel and ipecacuanha, of each a quarter to half a grain every three or four hours, to infants from two or three weeks to two or three months old, a grain of each to those from three to twelve months, less or more, according to the strength of the child and severity of the symptoms. Should the first dose produce vomiting, and several others be retained, so much the better; occasional vomiting, when not severe, is rather in favour of than against the treatment, as much viscid mucus is discharged thereby. As the cough, difficulty of breathing, and other symptoms, are generally worse toward evening and during the night, followed by a remission toward morning and during the day, the calomel and ipecacuanha ought to be given as above while the severity of the exacerbation continues; and from a third of a tea-spoonful to a full tea-spoonful of the following mixture, every two or three hours during the remission:—℞ Potassio-tart. antim. [illegible], ʒij, vini [illegible], ʒj; sol muriat morphiæ, tinct hyoscyami, āā m xx.; syr. tolu, ℥ss; aquæ, ℥iss. M The rectum should be cleared out with warm water-and-milk, and the child placed in bed, with its head and shoulders elevated, otherwise the efforts to cough and expectorate may never be effectually accomplished. The nurse should also lie in bed with it, especially during very cold weather, in order to maintain the proper degree of warmth, which is much better than heating the air of the room to the temperature frequently required. This plan will succeed in recent and not very severe cases, or in the first stage of the disease. But should the case become worse—face livid, eyes closed, breathing still more frequent, short, and gasping; nostrils widely dilated with each inspiration, heaving of the chest and shoulders, the air scarcely penetrating the bronchi, which are filling fast with secretion, every expiration being succeeded by a [illegible] moan; inability to take the breast; [illegible] it is still highly proper [illegible] the use of [illegible] and ipecacuanha [illegible] will [illegible] blistering the chest [illegible] with perfect safety, while the loss of a very small quantity of blood would speedily [illegible] termination, by prostrating what remains of the vital powers. Mr. Thomson says, he has several times seen fatal effects from loss of blood by leeches applied to infants under twelve months, in this and other diseases; while he has never seen any danger arise from blistering very young infants with the common cantharides plaster, applied to the bare skin without any interposing substance The "severe sloughing" and other mischief which sometimes take place, must be, he thinks, in consequence of culpable neglect in allowing blisters to remain on until they produce an "escharotic," and not simply and solely a rubefacient effect This can be effectually produced by leaving the common blistering plaster (spread thin on fine cotton or white calico, and its surface smeared with olive oil) on until the skin becomes red, which will happen in two, three, or four hours, according to the age of the child, strength, and temperature of the skin. A soft warm poultice, in a muslin bag, oiled, ought then to be applied over the reddened surface for two or three hours, when the cuticle will be found elevated half an inch, and full of serous fluid, and great relief afforded to the little patient. The blistered surface must be dressed, until healed, with lard, fresh butter, or any simple unctuous substance, spread on very fine cotton. The practitioner should not order a blister to remain on an infant for a definite period, but direct its removal as soon as redness is produced, which the nurse can easily ascertain by paring its edge occasionally Of course, the acetum cantharidis has its advantages, but it cannot be applied under every circumstance. As soon as the more dangerous symptoms have been subdued, the use of the above mixture ought to be resumed or commenced, and if given at bedtime, and during the night if required, it will procure rest and promote expectoration.

ELEPHANTIASIS.—Mr. Biscome considers elephantiasis to be the sequela or degeneration of some other disease, generally from repeated attacks of erysipelas or from a want of tone in the lymphatics, induced by a sort of sub-inflammation When it arises from erysipelas, it is generally more or less complicated with visceral disease, it is more local in its character, when it results from the last named cause. When the sequela of erysipelas, it is not until after repeated attacks of that disease, and longer persistence of each attack, that enlargement of the part ensues, the inflammatory action at each accession seemingly penetrating deeper, involving the whole of the subcutaneous cellular substance, producing infiltration of that tissue, and, ultimately, extensive partial disorganisation, which, degenerating into a variety of shapes, becomes studded with stone-like excrescences or protuberances, intersected, especially about the instep and ankle, with weeping fissures or rhagades, partaking of a sandy or horny appearance When it commences in the lymphatics, a weariness is felt along their course in the limb and a numbed sensation, as though it were (as it is termed) asleep, a dull, deep-seated, gnawing pain is always present, causing a sickening at the stomach, amounting sometimes to vomiting, and unfitting the patient for general exertion. It is unattended by fever or discoloration (rosy-blush, as in erysipelas); the pulse is small, feeble, and frequent, tongue pale, or white, and the limb imperceptibly enlarges, assuming a doughy feel, the temperature being lower than natural Should the scrotum be fastened on, a puffiness and intolerable itchiness are present, and if the surface be abraded by scratching or otherwise lymph exudes profusely therefrom, forming crusts, which, adhering firmly, induce an unpleasant prickly sensation when in contact with the clothes. The parts, by-and-by, become [illegible] into lumps, and run into one [illegible] mass, attaining, in some cases, to an enormous size, with so little sensation as to admit of its being kicked about like a foot-ball; in one case, when amputated, the scrotum weighed ninety-two pounds avoirdupois, filling a pork-barrel! A leg which Mr. Biscome amputated above the knee, having been dissected, the disease seemed to have been seated in the subcutaneous cellular tissue, the muscles, ligaments, &c., being apparently comparatively sound, the infiltrated or hypertrophied substance at the back of the leg, the calf, measuring six inches and a-half in depth or thickness, consisting of a fatty bacon-like substance, with few bleeding vessels The bloodvessels (veins) above the knee, where the knife was applied, were unusually large, admitting, at the onset of the operation, of such a rush of blood as to give for the moment the idea that the artery was not properly under command On the inspection of a scrotal tumour, in which the

substance was very similar to that of the leg, it was found to be interspersed with hydatid-like forms, from which, when cut into, a tenacious transparent fluid escaped.

Partial Sloughing of the Penis.—Three cases of partial sloughing of the penis are reported from St. Bartholomew's Hospital. In the first case, that of a stout, healthy labourer, the mortification evidently resulted from the intensity of the inflammation of the organ. Hemorrhage occurred to a considerable extent, on two occasions, from a sloughing sore on the glans and body of the penis, which was exposed by the division of the prepuce. The patient recovered, but lost one-third of the prepuce, and two thirds of the glans, having besides an abnormal opening into the urethra, at about a quarter of an inch from the natural orifice, by which the greater part of the urine passed. In the second case, a lad of weakly habit, the mortification, which was to the extent of a five-shilling piece, may be referred to want of tone of the system. He was pale and anxious, the pulse feeble, and the extremities cold, with a white tongue, no appetite; no sleep. Mr Lawrence immediately divided the prepuce in its whole superior length, an operation which did not cause the loss of much blood. There was a spreading sloughing sore, which had destroyed three-fourths of the glans penis, and the whole internal lining of the prepuce was mortified. The apex of the glans, containing the orifice of the urethra, was still sound. The treatment consisted in the exhibition of opiates, stimulants, tonics, and nourishing diet; in a few days the slough separated, the whole of the prepuce and four-fifths of the glans penis being destroyed, but the urethra being quite uninjured. The wound granulated healthily, and about six weeks afterwards he was discharged, with the wound nearly cicatrised. The third case is one of phagedenic and sloughy sore, also dependant on want of tone, apparently caused by habits of dissipation. The prepuce was divided, the reason for which is not clearly assigned, and the man supported by good diet, &c. The treatment pursued was rather vacillating, and the progress of the case equally so, but ultimately under the use of dietetic tonics and the local application of a solution of nitrate of silver, the man recovered. He was afterwards re-admitted with secondary symptoms. After detailing these cases, Mr Holmes Coote, by whom they are reported, remarks that the thin integument, which is reflected from the inner surface of the prepuce, over the glans penis, affords a very inconsiderable protection against the venereal poison; hence, primary sores most commonly occur in this situation. Whatever may be their form, they are, for the most part, readily amenable to ordinary treatment. Circumstances, however, may entirely change their aspect, and convert the ulcerative into a sloughing process; the venereal poison is then destroyed by the activity of the local disease, and the patient recovers with a mutilated organ, but free from risk of secondary symptoms. The causes of sloughing may be arranged under three heads —1. Neglect on the part of the patient, in a constitution enfeebled by intemperance or insufficient food. 2. Acute inflammation of the part. 3. Some unfavourable relation between the constitutional powers of the patient and the venereal poison, giving to the latter an especial virulence. The occurrence of acute inflammation is a very untoward ... the glans penis swells, and becomes ... the inflamed and swelled prepuce, and ... tion or sore, inclosed between two opposed mucous surfaces, rapidly assumes an unfavourable aspect. The discharge, losing its puriform character, becomes ichorous, or sanious, and offensive in smell; sloughing next ensues, which may involve, not only the glans, but also the whole inner lining of the prepuce. This rapidly destructive process, extend to some large arterial trunk before nature has time to plug the tube, leads to violent and uncontrollable hemorrhage. If the prepuce be not divided early, it mortifies, and thus liberates the glans, the slough upon which separates, and generally leaves a healthy granulating surface. It occasionally happens, however, that the liberation of the glans is not followed by such marked improvement; the sloughing process goes on until the whole glans is destroyed, and the extremities of the corpora cavernosa are denuded. Considerable judgment is required in the treatment of these affections. If local congestion exist, it must be relieved; the sore must be liberated from pressure, the pulse restored to its natural standard, and the nervous system quieted. The two first objects are attained by the division of the prepuce; the arteriæ dorsales penis divide, and form a ring around the corona glandis; two sets of branches are given off, one to the glans, the other to the prepuce. Division of the latter at once abstracts blood from the former. But how is it to be known when a sore is about to slough under a prepuce, inflamed, swollen, and contracted at its orifice, so as to be incapable of withdrawal? The discharge, losing its puriform character, becomes ichorous or sanious, and extremely fœtid, and flows from under the prepuce in great abundance. The least pressure upon the exterior causes intense pain, the patient generally exhibits febrile symptoms, and the pulse is full, hard, and bounding. When mortification to any extent has ensued, with the same local symptoms the pulse rapidly sinks, and the patient becomes feeble, restless, and dejected. The glans penis is more completely liberated by division of the upper than of the lower half of the prepuce; but the latter section is sometimes preferred, in consequence of its causing less deformity. When the sore has been liberated, and the bleeding has ceased, a warm bread-and-water poultice is the best application. Febrile symptoms, if present, must be subdued by suitable remedies, and by low diet. If the patient is feeble and depressed, stimuli and liberal diet may be necessary, as in the cases here related. Pain must be quieted and rest obtained, by the judicious employment of opium, and the patient must be put in a roomy and well-ventilated apartment. The general constitutional disturbance marking the progress of these cases contra-indicates the employment of such a remedy as mercury, the action of which is of itself sufficient to produce a state of irritable feverish excitement.

Nitrate of Silver in Venereal Sores.—Mr. Acton states that experiments on inoculation have incontestably proved, that if caustic be employed soon after the receipt of the virus, all further effects may be stayed; they have, moreover, shown that up to the third day the disease is of a local nature, entirely confined to the parts with which the virus has come in contact, and that it is not necessary to cauterise beyond the extent of the ulcer, but that, on the contrary, the doing so is fraught with great mischief. A patient, thinking he can treat his own case, and following, as he believes, his surgeon's plan, employs nitrate of silver most bountifully; great pain is produced; a deep eschar comes away in the course of a few days, the irritability of the organ is greatly increased; and being unable ... over the glans, the patient seeks the assistance ... his surgeon, who, after carefully examining the parts, finds the original sore re-inoculated, and perhaps several other small ones in the neighbourhood. Such cases clearly show that the employment of caustic may often do more harm than good; that while the nitrate of silver destroys the virus of one ..., the irritation it produces prevents our seeing the mischief accruing to others; and probably the non observance of these rules leads to caustic being much abused. If a surgeon will inoculate a man, and watch the effects, he will find that at the commencement he can destroy effectually the virus by the slightest touch of the salt; little or no irritation will follow, and the application may be repeated at intervals. Before the nitrate of silver is employed, the part should be carefully cleansed by being soaked in warm water, for the virus may exist on the surface of the neighbouring skin, and if not washed off will re-inoculate the sore when the little eschar falls, and undue blame will be thrown on the caustic. Although no other ulcer exists at the time of using the salt, frequently in a few hours after, another sore, or a little pustule, will be met with, which, if precaution be not taken, will go on increasing, and the disease will spread rapidly. These circumstances explain several anomalies which have thrown discredit on caustic. The parts should be carefully dried, ... it be an excoriation the surgeon is called on to treat, the skin should be put on the stretch, and the ... stick of nitrate of silver ... lightly passed across it, so as effectually ... the surface in its entire extent, all cracks and crevices must be treated in the same way. If a pustule exist it should be opened with a lancet, the pus evacuated, and a pointed stick of the nitrate of silver introduced, so as to cauterise the walls of the pustule. For this purpose the caustic should always be kept pointed; and this may easily be done, by wetting it, and rubbing its sides against a piece of soft wash-leather. It is very difficult to obtain a point by scraping the stick of nitrate of silver, in consequence of the brittleness of the salt, but when once obtained, the caustic will retain its pointed character. If the surgeon is called upon to treat chancres at the orifice of the prepuce presenting the appearance of cracks, he must draw back the prepuce gently, when he will be able to cauterise the entire extent of the chancre, but in repeating the operation, let him ... d against breaking through the cicatrix, or this ... r chancre will extend; the same observation applying to the treatment of chancres of the frænum; to obviate the difficulty of healing such ulcers, Mr. Acton divides the frænum, and cauterises the entire of the divided surface. Without these precautions, it may be weeks before such sores are healed. Reliance must not be placed alone on the salt, and previous ablution, but extension of the disease should be stayed by lotions of an astringent kind; such as a solution of pure tannin, in the proportion of two grains to the ounce of water, which not only checks the discharge, but seems to tan or harden the skin: the private patient, however, should be told, that this solution slightly stains his linen with a brown mark, or the lotion may tell tales to the family; to obviate this, a weak solution of sulphate of zinc may be employed, or, if desirable, dry lint; but dry lint has the objection, in some instances, of irritating the part, and, moreover, the little eschar is a long time in falling, and the caustic cannot soon be re-applied. The caustic may be used once in the twenty four hours. The surgeon will occasionally be disappointed in finding chancres progress less favourably than here stated; in spite of all his attempts to cure them, caustic fails, this is more especially witnessed in ulcers situated around the narrow prepuce, at the frænum, orifice of the urethra, or fourchette in the female, it is the situation of the sore rather than the want of efficacy in the remedy that prevents cicatrisation; rest and attention to cleanliness, without rupturing the cicatrix, will alone bring about a cure, in these instances it is vain to continue the caustic; its objects can be no longer attained, and it produces much mischief.

Fracture of the Humerus.—Dr Bernecastle describes a case of fracture of the humerus occurring in a navigator from muscular action. The man had previously been the subject of rheumatism, especially affecting that arm. The bone united readily, and the patient is reported not to have suffered from his previous malady—rheumatism—afterwards. Six years previously he had salivated himself for gonorrhœa, but to what extent is not stated, nor is any information given respecting the presence of the signs of syphilis, or of the consequences of undue mercurialisation.

Disease of the Brain and Urinary Organs.—A case is reported from University College Hospital, of a man who was apparently first seized with symptoms of influenza, accompanied with intense headache, followed by bloody urine, which afterwards contained pus. This was succeeded by inflammation of the penis and corpus spongiosum, proceeding to suppuration; latent pneumonia also ensued, and the case terminated fatally. The examination of the body was made eighteen hours after death. It was rather emaciated; the walls of the abdomen contained about half an inch of fat; there was considerable cadaveric rigidity; there was no eruption or abrasion of skin; the muscles were of a dark, unhealthy colour. The calvarium and dura mater having been removed, a number of opaque spots were observed on the surface of the arachnoid; these were very generally diffused, extending backwards to the base of the brain; these spots varying from the size of a pea to that of a penny piece. Beneath the arachnoid was a small quantity of serum; the membrane peeled off readily. The pia mater was unusually injected; indeed, the whole brain appeared too vascular. On cutting through the hemispheres, a coagulum was observed, about the size of

a small pea, in the posterior lobe of the left hemisphere. There was no fluid in the ventricles; the choroid plexus was dark and unusually congested. A coagulum about the size of a small hazel nut was observed in the right posterior lobe of the cerebellum. The bronchi were rather thick and firm; there was a slight amount of emphysema at the apex and margins of the left lung; there were some opaque tuberculous deposits at the apex of the right lung, but in the pleura posteriorly, covering the middle lobe of the right lung, was an opaque deposit, about the size of a shilling; this was very firm and resisting to the knife. Below this there was a circumscribed softening, of a dark colour, about the size of a hazel nut, with induration of the parenchyma around, intensely fetid, of a distinctly gangrenous odour. The seat of this morbid appearance corresponded to the situation of the dulness during life. Right lung weighed eighteen ounces and a half; left, sixteen ounces. The heart was large, pale, and softer than usual; the aortic valves were slightly thickened; the left side contained a very small coagulum of fibrine; the right side was empty. The pericardium contained about six ounces of serum. Weight, twelve ounces and a half. The spleen was quite pale and soft, and broke down under the finger with the greatest ease; it was much larger than usual. Weight, fourteen ounces and a half. The gall bladder was very large; the texture of the liver itself was firm; there was a small opaque spot on its surface. Weight, three pounds eight ounces and a half. The left kidney was much congested, not generally granular, but here and there, on its surface, were a number of white spots, about the size of a pin's head. Some of these came away with the capsule; others did not, but could be easily turned out with the point of the knife, not being, apparently, adherent to the cortical substance. The right kidney was rather more congested than the left, and also contained many serous cysts. The stomach was healthy; the small intestines were also healthy, excepting here and there patches of ecchymosis. About the middle of the jejunum was a constriction of the gut, which, however, would admit the index finger; there was no thickening or other morbid appearance about the constriction. The ascending and transverse colon were healthy, but small. In the descending colon there were three constrictions, and the mucous membrane at these parts was indurated, and exhibited marks of cicatrisation. At the commencement of the sigmoid flexure was a stricture that would not admit more than a goose quill, and two inches lower down, a similar stricture; the gut was bent upon itself at both. On cutting open the former, three ulcers were observed; one larger, about the size of a small bean, placed longitudinally to the axis of the intestines, and two smaller. Portions of the edges of these had begun to cicatrise, and caused corresponding wrinkling of the mucous membrane. The centre of these gave an appearance as if the mucous, submucous, and muscular tissues had been removed by a punch, the peritoneal investment only remaining entire. The lower constriction presented equally the same general characters, but only the ulcers were smaller and more numerous. Dissection of the penis: About three inches down the urethra, situated posteriorly (in relation to the pendulous state of the organ), was a ragged opening, about an inch long, such as might have been produced if it had been torn by a blunt instrument; this communicated posteriorly with a large abscess that would admit the finger, extending downwards to the bulb, and upwards to the glans; it contained grumous, bloody pus. The posterior wall of the corpus spongiosum was much thinned. On a closer examination, it was found that the corpus spongiosum had been in most parts disintegrated and broken up by the pus, there being no pyaline membrane to circumscribe the latter The membranous portion of the urethra was rather narrower than usual, and several openings, of about the size of large pins' heads, were observed on the floor of it; two especially large, situated one on each side. These, however, were found to be mere sacs, not deeper than a quarter of an inch. On squeezing the prostate, a number of other smaller openings were observed in the same part, giving exit to what appeared to be grumous blood and pus. The left lobe of the prostate was hollowed out into a ragged abscess, about the size of a walnut, and several smaller abscesses seemed to open into it. These abscesses did not communicate directly with the urethra, but opened first in the prostate ducts. The muscular structure of the bladder was hypertrophied; the lining membrane healthy; the uvula unnaturally prominent.

ORIGINAL LECTURES.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

BY G. J. GUTHRIE, F.R.S., &c.

LECTURE III.

There are few points in surgery on which a greater difference of opinion has taken place, than on the best manner of placing a ligature on an artery, and on the effects which follow its application.

When a round and small ligature is properly applied to an artery of a large size, such as the femoral, the sides of the vessel are brought together in a folded, plaited, or wrinkled manner; the inner and middle coats of the artery are divided, the outer one remains entire and apparently unhurt. If the ligature be removed, an impression or indentation made by it on the outer coat will remain as a mark; and if the artery be slit open in a careful manner, the division of the two inner coats will be obvious. These changes were known to Desault, and are mentioned by Deschamps in his work on the Ligature of Arteries. They were more satisfactorily proved to occur by Dr. Jones, and have been clearly stated by Mr. Hodgson and others. The remaining part of the process differs from the account they have given, and from observations I have had opportunities of making on the living and the dead, is as follows:—The inner and middle coats are not only divided, but the inner one particularly appears to be curled inwards on itself, so that the cut edge of one half or side is not applied to its fellow in the usual way of two surfaces, but by curling inwards meets its opponent on every point of a circle, and in this way forms a barrier inside that of the external coat, which is tied around it by the ligature: so that in fact when a small ligature is firmly tied, its direct pressure is not applied to the inner coats, which have been divided, and have curled away from it, but to the outer one, which is in consequence of that pressure to ulcerate or slough, which processes could scarcely fail to take place also in the other coats, if they were subjected to pressure in a similar manner. The cut edges of the two inner coats, being from this provision of nature perfectly free, are capable of taking on the process of inflammation, which stops at the adhesive stage. This they do by the effusion of lymph or fibrin both within and without, to a greater or less extent, as the case may require. The outer coat of the artery must either yield by ulceration or sloughing, or the ligature must remain until it is decomposed and destroyed. The artery usually yields by sloughing, and the ligature is left at liberty by the ulceration which takes place in the sound part of the artery immediately above and below the part strangulated by the ligature, and which part is frequently brought

in the noose. The artery does not always

by sloughing, particularly if a large one, and the ligature has been thick and soft. In this case, a part of the outer coat, from its folding or plaiting under the ligature, seems to escape that degree of pressure necessary to destroy it, and when the remaining part yields, it remains entire, and is only removed by a subsequent process of ulceration, oc-

tation as an extraneous body. I have had the opportunity and the misfortune of examining great numbers of stumps after amputation and death, and I have seen this occur in so many instances as to leave no doubt of the fact.

In these cases, the external coat could not close around the inner ones; and this shows that they are capable of forming an effectual barrier without it, although it materially assists in giving greater strength to the cicatrix, by the effusion of fibrin which takes place within, without, and around.

Whilst this process is going on without, and at the very extremity of the artery, the vessel is gradually contracted above it, and its coats become more or less inflamed, soft, and vascular. The inner coat is seen to be wrinkled transversely, and a small coagulum of blood is formed within it. This sometimes completely fills the artery, but it is more common for a small tapering coagulum to be formed, adhering by its base to the extremity of the inner coat; the white colour of which renders it distinctly observable, when contrasted either with the coagulum, or the inner coat of the artery, which latter is usually of a red or scarlet colour, whilst the inflammatory action is going on. My observations have led me to believe that a coagulum is not absolutely necessary to the permanent closure of the artery, although it certainly assists in maintaining it. An artery is also supposed to contract gradually up to its first collateral branch; but this is not always the case, and depends entirely on the use for which the branch is required. After amputation at the middle of the arm, the artery will go on diminishing in size up to the subscapular branch; the circumflex arteries diminishing in proportion, in consequence of their being so much less necessary than before the operation. I have seen several instances in which the principal artery has remained pervious below the collateral branch, the next immediately above the part where the ligature has been applied. Neither will the presence of a collateral branch immediately above where the ligature has been placed upon the artery always interfere with the consolidation of the wound, and the closure of the canal of the vessel. It may impede the process, and render it for a time less safe, and in some instances prevent it altogether. I have so often seen large arteries heal after division close to the giving off of a considerable branch, that I consider them to be always capable of doing so, provided they are naturally sound. If they are not sound, it is very doubtful what process may take place; but it will be less likely to be a healthy one, if interfered with by the immediate proximity of a collateral branch. The power which suppresses hemorrhage in a bleeding artery, resides however in the extremity of the vessel itself.

A ligature should always be round and small; provided it be sufficiently strong. The strength of a ligature is variously estimated; some surgeons trying it by the strength of their own fingers, others by what they conceive to be the resisting power of the coats of the artery, in which perhaps they may err. The only way in which a surgeon can hope to acquire correct information on this point, is by trying on the dead body what force of fingers is required to cut the inner coats of arteries of various sizes; and then taking the least force required for this purpose, to ascertain whether he can easily pull the ligature over, or off the divided end of the artery. If a surgeon will take the trouble to do this, he will find that he has estimated the necessary force much too highly, and that he is in more danger by breaking his ligature than of failing to secure the artery. Hemorrhage has however been known to occur from the ligature having slipped off the end of an artery, which had been divided in the operation for aneurism, although I have never seen it happen after amputation, where the vessels were tied with a small firm ligature. It constitutes a valid objection to the division of the artery between the ligatures, when two are applied.

A ligature composed of one strong thread of dentist's silk, well waxed, is sufficiently firm for the largest artery. It does not however much signify what may be the shape, size, form, or substance of ligatures, when they are applied to arteries in a sound state, provided they are not too large, are fairly and separately tied, and with a sufficient degree of force to retain the ligature in its situation until separated by the usual processes of nature, which generally take from fourteen to thirty days for their completion.

When arteries are unhealthy, the selection and proper application of a ligature are points of great importance. A small round ligature should be fairly, evenly, and firmly although not too forcibly applied, without the intervention of any substance whatever between it and the cellular covering of the artery. The secondary hemorrhages, which are recorded by different writers, took place I am disposed to

believe, more from the application of improper ligatures than from any other cause; for the inner coat of an artery is so prone to take on the adhesive state of inflammation, that if a strong small ligature be applied in the manner directed, it is more than probable that the closure of the artery will be effected. Ulceration will however sometimes take place on the inner coat of the vessel, and slowly extend outwards, undoing in its progress any steps which may have been begun for the consolidation of the extremity of the artery. When a secondary hemorrhage does occur from this or any other cause, it is usually from the beginning of the second to the fourth week, but there is no security for the patient until after the ligature has come away, unless it is retained an inordinate length of time from having included some substances which do not readily yield under irritation, such as the extremity of a nerve, or a slip of ligament which is not sufficiently compressed in the noose of the ligature.

Secondary hemorrhage may also take place from the extension of ulceration or sloughing to the artery from the surrounding parts, and perhaps as frequently as from any other cause, but when mortification occurs, there is no secondary hemorrhage, unless in that species which is called hospital gangrene. The advantages to be derived from the application of a strong small ligature, from the least possible disturbance of the surrounding parts, and from absolute quietude, whilst the healing processes are going on, must be so obvious as to require no further observation. Secondary hemorrhage has been shown to be the consequence of motion of the limb at too early a period, and an undue interference with the ligature, by pulling at it, cannot be too earnestly deprecated, as likely to give rise to it in a similar manner.

I omitted to mention in my last lecture a case I had related, which is so similar to Mr Keate's, and which was conducted on such sound principles that it deserves your utmost attention. It is given by Mr Bell, of Great Grimsby, in the Lancet, page 801, vol. xxxi, 18[illegible]0.

Case 32.—A young man of sixteen was wounded on the inner and lower part of the thigh by a pen knife, and lost a considerable quantity of blood, which was restrained by compress and bandage, and the young man was kept in bed for three weeks, when a profuse bleeding took place, which was again suppressed by his bandages. He suffered severe pain during the night, and the next day the formation of a swelling at the wounded part was evident. Three more bleedings took place, the swelling increased so as to occupy two thirds of the inner aspect of the thigh, and exactly one month after the accident it was decided in consultation that the artery should be secured. Mr Bell made an incision between five and six inches long, taking the original wound as a centre, removed all the fluid and coagulated blood, placed a ligature above and then below the opening in the artery, and closed the wound. The young man perfectly recovered, the limb two years afterwards being in no way deteriorated by the injury.

The younger Louis, in his Memoire sur les tumeurs fongueuses de la dure mère, page 3, published in the Memoires de l'Academie de Chirurgie de Paris, says, "Our knowledge, always too limited, is almost necessarily defective when it is not supported by a sufficient number of facts relating to the same object, which should be examined with the most scrupulous attention in all their different bearings." Sensible of the justice of these remarks, they must form my apology for the production of so many nearly similar cases, under the belief that they are essentially necessary for a due understanding of the subject to which they relate. They are all abridged to the utmost, consistently with a due preservation of their sense and meaning.

The brilliant theory of the cure of aneurism by the Hunterian method, and the more brilliant operations which followed it, superseded and almost obliterated from the minds of modern surgeons the recollection of the ancient method of proceeding with respect to wounded arteries. There was not a single surgeon to be found with the army at the first battle in Portugal in 1809, who doubted for an instant the propriety of its application to them, no matter in what school they had been educated, nor in what country they had practised their profession. I partook of the general persuasion which at that time prevailed in England, but was fortunately on the very first occasion at the battle of Roliça led to doubt, and shortly afterwards was convinced not only of its inapplicability but of its inefficiency.

Case 33.—Corporal Carter, of the pioneers of the 29th regiment, was wounded at the battle of Roliça in August, 1809, by a musket-ball, which passed through the anterior and upper part of the forearm, fracturing the ulna. Shortly afterwards a profuse hemorrhage took place, and the staff surgeon in charge tied the brachial artery. In the night the hemorrhage recurred, and the man nearly bled to death. The arm was then amputated, when the ulnar artery was found in an open and sloughing state.

Remarks.—A simple incision to expose the wounded artery and to place two ligatures upon it would have saved this man his arm.

Case 34.—At the battle of Vimiera, which followed a few days afterwards, a soldier received a somewhat similar wound, save that the brachial artery bled forthwith, and was only stopped by the tourniquet. Warned by the preceding case, I cut down on the artery, carefully avoiding the nerve, which had been tied in the former instance, and found the artery more than half divided. It was secured by a ligature above and below the wound, the bleeding did not afterwards return, and the man recovered.

Case 35.—Thomas Carryan, of the 3rd regiment, was wounded at Albuhera, on the 16th May, 1811, on the inside of the calf of the right leg, the ball passing out on the fore and outside of the tibia. It bled considerably for some minutes, when it ceased, and the hemorrhage did not return until the 15th of June, on which day a little blood followed the dressings, and increased on the patient making any exertion; so that, on the 4th, the gentleman under whose care he was, tied the femoral artery on the outside of the sartorius muscle, which suppressed the hemorrhage for that day, the limb continuing with little or no interruption of the same temperature to the hand as the other; on the 5th, the original wound had a bad appearance, and some coagulated blood was readily pressed out of it; on the 6th, a greater quantity came away, and, on the 7th, the exertion of using the bed-pan was followed by a stream of arterial blood, which ceased on tightening the precautionary tourniquet.

The limb was amputated above the ligature on the artery. Its dissection showed the anterior tibial artery to have been destroyed for some distance, and the muscles on the back part of the leg nearly in a gangrenous state. The patient died a few days afterwards.

Remarks.—If an incision had been made on the leg so as to expose the artery, and a ligature had been placed above and below the wound, the man would not have died, as far as surgery was concerned.

Case 36.—A private of the 5th division of infantry received a wound at the battle of Salamanca, from a musket ball, which passed across the back part of the right leg, from above downwards and inwards. It entered about two inches below and behind the head of the fibula, and passed out near the inner edge of the tibia. "There was little blood lost at the time, and it was considered to be a simple wound; eight days after the injury, some blood flowed with the discharge; this increased during the night, and on examining the limb on the morning of the ninth day, it was evidently injected with blood, which flowed of a scarlet colour from both orifices. It being doubtful which vessel was wounded, whether it was the trunk of the popliteal artery, or the posterior tibial or peroneal after its division into these branches, it was thought advisable to place a ligature on the femoral artery about the middle of the thigh, which suppressed the hemorrhage. The case was now shown to me, as one in proof of the incorrectness of the opinion I had a few days before stated, of the impropriety of such an operation being done. The seeming success did not long continue; a hemorrhage again took place from the original wound, and the limb was then amputated. The posterior tibial artery had been injured, and had sloughed. The man died."

Remarks.—A straight incision directly through the back of the calf of the leg of six inches in length, and two ligatures on the artery, would have saved this man's leg and life.

Case 37.—James Murphy, of the 28th regiment, twenty-two years of age, was wounded at the battle of Waterloo by a musket ball, which passed through the thigh below its middle and in the course of the femoral artery, which was not, apparently, wounded at the time; but as the wound began to heal, it gave rise to an aneurismal swelling in the part, for which the usual operation for aneurism above the seat of injury was performed by Staff-surgeon Cole, on the 22nd of July, 1815, two ligatures being placed below the artery, which was divided between them.

On the 11th of August, matter was evidently collecting in the thigh, and on the 13th a counter opening was made at the inferior part of the thigh, in the line of the aneurismal tumour, and over the exit of the ball, and two ounces of a bloody purulent fluid were evacuated; four ounces of blood were lost in the evening from the wound.

25th. This morning, on rising to get out of bed, an arterial hemorrhage took place from the counter opening to the amount of about four ounces; pressure on the thigh by the tourniquet could not stop it, but it was arrested by compress and bandage and the application of cold. The thigh in the evening appeared to be swollen.

26th. The bleeding recurred this morning, but was again arrested by pressure, but the thigh is enlarged and seems injected with blood. Amputation was now determined upon, and performed. The man sunk and died two hours and a half afterwards.

Dissection.—An incision was made in the direction of the aneurismal wound about an inch deep, which exposed the sac, containing a large quantity of coagulated blood of a dark colour, although destitute of fetor; the blood was not confined to the sac, but was extravasated throughout the limb, the quantity altogether being at least one pound and a half. Another incision was made towards the knee, somewhat in the direction of the artery, and upon opening the tumour, which was beneath the fascia, there spouted out three ounces of thin matter of the colour of clay. No communication whatever could be found between this abscess and any other part.

The ball had passed through the rectus, vastus internus, and sartorius muscles, beneath the abscess but higher in the thigh, and immediately over that part of the artery which was diseased, but did not touch it, although it was the cause of disease in the parts around the artery and of the vessel itself, but the injury was not sufficient to bring on immediate hemorrhage. The artery was affected by extension of disease to it, and not by the direct contact of the ball, in the track of which nothing peculiar was observable. It communicated with the counter opening, and with that part where the blood was first effused.

Remarks.—The great error lay in making a new wound, and in tying the femoral artery as for an aneurism, instead of laying open the swelling. If this had been done, the man's leg and life in all probability would have been saved.

The Hunterian theory, the cause of death in these three men, as well as in many others before and since, is founded on the fact that the artery is, and has been for some time, in a diseased state immediately above and below the aneurismal sac—that if the sac were opened, or caused to inflame or to suppurate, the artery could not be safely tied where it was diseased; that it is more likely to be found in a sounder state at some distance from the aneurismal tumour; that the operation is more simple when performed on parts in a healthy and natural state; and that the impetus of the circulation being taken off by the ligature, the blood in the shut sac would become stagnant, and consequently coagulate, and be ultimately absorbed. When the theory is applied to the treatment of a wounded artery, even with a narrow, [illegible] an open wound, the absence of a [illegible] sac [illegible] any regurgitating blood from the collateral or capillary vessels is overlooked, together with the hemorrhage which must necessarily follow from the want of such a retaining membrane, unless the divided ends of the vessel should have been closed by some accidental rather than expected process of nature, before the collateral or capillary circulation could become efficient. The

previous soundness of the artery at the part injured is overlooked; the danger of mortification from a deficient collateral circulation is contemned, and even if the external wound should have closed, which is not commonly the case, the fact of its being a spurious diffused aneurism, without a sufficiently restraining sac, is neglected. The unaccountable and absurd fear of hemorrhage on opening such a sac, after the numerous instances which are recorded proving its unworthiness, is only equalled by the no less strange and more unaccountable fear which still pervades the minds of many surgeons, of cutting through muscular fibres in order to expose an artery. These apprehensions are so truly ludicrous, that it appears to me almost incomprehensible, that they can have been so long entertained by able anatomists and surgeons. Nevertheless, they are the only reasons which can be given for placing a ligature on the internal iliac for a gluteal aneurism following a wound, or indeed on any other artery which has suffered a similar injury.

In order to make the necessity for abandoning all fear of hemorrhage from such aneurismal swellings manifest, and to show how imperative it is that even whole muscles should be divided, if they interfere in the progress of an operation, I shall first take into consideration wounds of the arteries of the hip and of the leg, and of the aneurismal swellings to which they may give rise.

Mr. J. Bell was the first to set the memorable example of dividing a large portion of a muscle to enable him to reach a wounded gluteal artery which he did not think he could attain by any other means. His vivid description of an incision of eight inches long, afterwards said to be enlarged to two feet (in what direction is not stated), the removal of eight pounds of coagulated blood from the sac, the deluge of fresh arterial blood which followed with a loud whizzing noise, after all which the patient recovered, ought to have allayed the apprehensions of the most timid surgeons; and although Mr. J. Bell's dramatic sketch of his leech catcher's case may be somewhat exaggerated, it ought to have made surgeons think more on these points than many appear to have done or even to do; and it should have induced them to perform such operations sooner, when the parts would be less distended, and more readily distinguishable.

This operation has since been done by Dr. Murray in Spain, Messrs. Rogers of the United States, Carmichael of Dublin, and Baroni of Bologna; and as the operations performed by the two last are as simply described as Mr. J. Bell's is fearfully related, I shall give them as shortly as possible.

CASE 38.—Lieutenant Colonel M'Pherson, 92nd regiment, received a wound from a musket-ball on the 13th of December, 1813, which entered a little in front of the trochanter major of the left side, struck the os femoris which flattened it, passed underneath the glutei muscles, along the ilium for about three inches, and lodged in the posterior part of the gluteus maximus, whence it was cut out next day. He continued to go on well and to recover his strength till the 27th of December, when he began to complain of pain and heat deeply seated in the wound, and was a little feverish and restless, for which he took a purgative and opiate at night, but without relief. On the 28th, the parts were observed to be more swollen, the pain was increased, and about noon a sudden and violent hemorrhage ensued from the posterior wound, by which in two or three minutes he lost upwards of two pints of blood. Compression was made on the mouth of the wound for some time, which restrained the flow of blood externally; but it appeared that hemorrhage was still going on internally. A firm hard compress of paper rolled up in a bandage was placed along the course of the posterior part of the wound, and bound tightly on it; the parts were kept very cool with vinegar and water; and gentle manual pressure, by a relief of servants as they became tired, was kept constantly on the pad, with a view to obliterate the artery. In the afternoon, a swelling about the size of an egg in extent, but not so thick, was observed to be forming below the pad, two inches from the orifice of the wound; he had for some time begun to feel a gradual increase of pain from the pressure, and whilst changing his posture in bed, the orderly removed his hand for a moment, when another gush of coagulated and of arterial blood escaped, which weakened but gave him ease.

29th.—The parts were considerably swelled, tense, and of a glassy appearance about the centre of the course of the wound; and some blood forced its way out by the anterior orifice, to which an additional compress was applied. About four o'clock in the morning of the 31st, the pressure having been removed, as he was not able to endure it on account of the dreadful pain it gave him, another profuse hemorrhage took place; which reduced him so much that his extremities became quite cold, his countenance pale and shrunk, and his pulse was hardly to be felt. It was stopped as before. In the course of some hours he recovered his warmth, his pulse rose, he became tolerably hearty again and took some breakfast, but as it was evident that the bleeding was going on internally, at eleven, a.m., the operation for placing a ligature on the wounded vessel was performed by Staff-surgeon Murray. A large mass of coagulated blood forced its way out as soon as the incision was made, and was followed by florid arterial blood. The wound was immediately sponged out, and the pressure of two pads which had been placed on each side of the incision, having been removed a little, two large branches of the gluteal artery which had been cut in the first incision, presented themselves, and were secured. The parts were again cleaned out by a sponge; and in the course of the original wound, a large artery was found close upon the bone, from which all the secondary bleedings had taken place; it was included in a ligature, and all bleeding from that part entirely ceased. Its opposite orifice appeared to have been included in a second ligature, as the needle was passed nearly quite down to the ilium. Two other small muscular branches were afterwards taken up, and the lips of the wound then brought together by slips of sticking plaster, with a compress of lint on each side, and a flannel bandage to support the whole. Although he did not lose above four ounces of blood directly from the arteries by the operation, he became much exhausted before it was finished, and indeed we were not without some fears that he would have sunk during its performance. Fifty drops of laudanum were given to him, and he was left on his bed where the operation was performed. For some time he suffered from that anxious restlessness attendant on exhaustion and extreme debility, and from pain and irritation; but when by rest and a little nourishment the powers of the system began to recover from the shock, the equilibrium of the circulation to be restored, and the opium to exert its influence, he became very composed and easy; his pulse got up; his countenance recovered a degree of vivacity; he said he felt himself much better than before the operation, being more free from pain in the seat of the wound, and his mind was more at ease from the idea of the vessel having been secured; he got a tolerably refreshing sleep of three or four hours, interrupted only at intervals by starting.

January 1st, 1814.—He passed a tolerably easy night, slept at intervals, and took a little nourishment, but had also symptoms of great exhaustion with alternations of chills and flushings, and clammy perspirations, and now and then sickness and hiccough. The parts about the wound were comparatively easy, but hot; there was no oozing of blood; he took a mouthful of toast with a dish of tea to breakfast, was in good spirits, but inclined to doze and sleep much. During the day his appetite failed. Towards evening he began to sink very rapidly, and died at eleven o'clock, p.m.

Remarks.—On examining the state of the parts after death, it was found that no adhesion had taken place. It is evident that the operation ought to have been done in the first instance. The only cause of delay arose from the thickness of the muscular parts to be divided, and the dread which at that period filled the minds of most surgeons upon this subject,—a dread which it is to be hoped will be for the future abandoned.

CASE 39, by Mr. Carmichael.—Master West, aged seventeen, eleven days before my visit received accidentally a wound of a penknife on the right hip, which penetrated as far as the handle would permit it to go. An immediate gush of blood followed, so strong as to dash against the wall of the chamber near to which he was sitting. Three days afterwards the patient imprudently walked down stairs, but had scarcely returned to his room when he felt an acute pain in the hip, followed by an immediate tumefaction, which increased from day to day. The small cicatrix of the wound was situated about half an inch above the presumed situation of the upper margin of the ischiatic notch, where the gluteal artery emerges from the pelvis. No pulsation was evident to the eye, even on the most minute examination, but the strong pulsation of an aneurismal tumour was manifested to the ear, either by immediate or mediate ascultation. It was evident, therefore, that the tumefaction of the hip did not depend upon the presence of matter, notwithstanding the patient had been affected with frequent rigors from the period that the swelling took place, accompanied by a foul tongue and symptomatic fever; but that it was owing to an effusion of blood in consequence of a wound of the trunk of the gluteal artery, or one of its largest branches.

As I had known instances of wounds of large arteries healing under similar circumstances, although the limb was injected with blood, I deemed it right to give this patient a similar chance before recourse was had to operation. I therefore directed ten ounces of blood to be taken from his arm, as the tumour was painful, and the pulse quick and hard. Draughts containing tincture of digitalis were given every sixth hour; a cold lotion was applied to the tumefied parts, and absolute rest in the recumbent position enjoined. This plan, with occasional opiates to meet pain and uneasiness, was persevered in during five days, but no benefit was derived. On the contrary, the tumefaction of the hip and entire limb was obviously increasing, and an operation was necessary. The patient being placed upon a table, lying on his face, I commenced by making an incision five inches in length, beginning an inch below the superior posterior spinous process of the ilium, and about the same distance from the margin of the sacrum, and continued it in a line extending obliquely downwards to the trochanter major. The gluteus maximus and medius were then rapidly divided, or rather their fibres separated (as the incision ran in the direction of the fibres), to the same extent as that of the integuments. The coagulated blood forming the tumour then became apparent through the sac or condensed cellular membrane with which it was covered. This was divided the whole extent of the incision by running a buttoned bistoury quickly along the finger introduced into the sac, and its contents, consisting of from one to two pounds of coagulated blood, were emptied rapidly out with both hands into a soup plate, which it completely filled. A large jet of fresh blood instantly filled the cavity I had emptied; but the precise spot from whence it came being perceived, I was enabled by pressure with the finger, to prevent any further effusion, while that which had been just poured out was removed by the sponge. It was obviously the trunk of the gluteal artery, just as it debouches from the ischiatic notch, which had been wounded. I endeavoured, but in vain, to secure the artery by means of the tenaculum. I had then recourse to a common needle of large size, and with this instrument was immediately successful in passing a ligature around the bleeding vessel, and in preventing all farther hemorrhage. After having waited some little time to ascertain if the artery was perfectly secured, lint was introduced to the bottom of the wound, as it was not likely that union by the first intention would take place between the walls of the extensive cavity which contained the coagulated blood. The patient was then put to bed, and an anodyne given to him. Everything went on favourably after the operation. On the third day the external dressings were removed; on the fourth the greater part of the lint with which the wound was filled came away, followed by a flow of matter of a good quality. On the sixth the ligature came away as well as the remainder of the lint. From this period the matter continued daily to diminish, and the patient recovered.

CASE 40.—Professor Baroni, of Bologna, was called to a young man who was wounded in the right hip by a fall from a tree on his own pruning hook, which divided the glutei muscles, laying bare the sacro-sciatic ligaments and the bone. The

edges of the wound united, but an abscess formed, requiring to be evacuated. The fourteenth day after the accident two most serious hemorrhages took place, which were restrained by compression. The wound being laid open, and the coagula removed, a jet of arterial blood marked the situation of the gluteal artery, the upper end of which was tied by the professor; but as the bleeding continued from the opposite end, a ligature was also placed on it, and the man recovered in a month.—*Gazette Médicale*, p. 695, 1835.

Remarks.—These cases are quite decisive as to the practice which ought to be pursued in wounds of the gluteal or of the sciatic arteries, or in aneurismal tumours, the consequence of wounds, in preference to placing the ligature on the internal iliac artery, as in a case of aneurism formed from disease of the coats of the vessel, to which operation, in such cases, the only real objections are, that the patient is likely to suffer from peritoneal inflammation, and that the operation is one of some difficulty, requiring a great degree of dexterity, and of anatomical knowledge.

Clinical Lecture,

BY DR. CORRIGAN,*

Delivered at the Whitworth, Hardwicke and Richmond Hospitals, Dublin.

Peritonitis—Fœcal Vomiting—Obstinate Constipation without Mechanical Obstruction—Explanation of Treatment, and Clinical Observations.

The case which I am about to read to you, Gentlemen, involves some points in practice which are still the subject of difference of opinion amongst the profession—I allude to the treatment of peritonitis.

Patrick Carroll, aged thirty-five, admitted on the 8th of March; had enjoyed very good health, with the exception of occasional wandering pains in the abdomen, until the night of the 27th of February, when, while sitting at dinner, he was suddenly seized with excruciating pain in the right lumbar region. To this succeeded shortly, abdominal tenderness, greatest in the pelvic region; the pulse became quick; he complained of thirst; the bowels were constipated, and the abdomen somewhat tympanitic. For these symptoms he had been attended previous to admission by Mr. Gorman, under whose care he was treated in the following manner:—

"He was bled to the amount of sixteen ounces, and put under mercury in the proportion of a grain every second hour; this was on the 27th of February, and the effect of the treatment was, that on the 1st of March the bowels were freely moved, the patient appearing to be very much better; the abdomen was ordered to be fomented, and the pills to be continued." This, you observe, was in three days after the commencement of the attack, at which time the man was very considerably better. "On the 2nd of March the improvement still continued, but at night all the pain of the abdomen returned with great severity, the surface was exceedingly sensible to pressure, the slightest touch being productive of extreme torture, and the tenderness being forced to extend all over the right iliac and lumbar regions. He was cupped over the painful parts, and several ounces of blood extracted, and the pills ordered to be continued. On the 3rd of March it appears this relapse had subsided, the mercury having slightly affected the mouth; the abdominal pain and tenderness were much relieved, the tympanitis, however, still remained, and an oil draught was ordered. On the 4th the gums were very sore, and the pain and tenderness completely gone. This was on the seventh day after the commencement of the attack, and the man expressed himself greatly relieved, so much, that his own expression was, he did not care if his belly were pressed down to the bone. He was at this time ordered a whiskey gargle for his mouth, with which he regaled himself by drinking in the course of the day, and the pain and tenderness became nearly as severe as ever in the evening."

Here, you observe, were two relapses of peritonitis within seven days, the first being most likely attributable to the same cause as the second, though no trace of this patient having similarly indulged himself was discovered. The mercurial pills were continued, and leeches applied to the abdomen, and on the 5th and 6th he was so much better, that the medicines were ordered to be discontinued. On the 7th the right iliac region was observed to be swollen, together with considerable pain on pressure; for this leeches were applied, and on the 8th he was admitted to the Whitworth Hospital. When first seen he rested in bed on his knees and elbows, groaning loudly, and apparently in great agony, and it was with much difficulty that he could be persuaded to turn on his back for the purpose of examining the abdomen.

The principal source of distress was referred to the pelvic region; at the lower and right side of the abdomen the tenderness was very great, and extended up on that side as far as the liver.

As the patient lay in bed, the abdomen seen in profile presented a waving outline, whose convexity rose to the height of several inches in the umbilical and pelvic region, while the line extending from the umbilical to the ensiform cartilage was hollowed. The respiration was now accelerated; pulse 120, slightly compressible; bowels constipated. He stated that he had not passed urine for some hours, but it was drawn off without difficulty. The head and upper part of the chest were covered with cold clammy perspiration. Leeches were applied to the abdomen, and two grains of mercury with a quarter of a grain of opium given every third hour.

On the 9th he felt better; the pain was gone, but the tenderness on pressure still remained; there had been some slight evacuation of fæcal matter. On pressing over the right iliac region, an elastic tumour was perceptible, and, on pressing more deeply, a small tumour, solid to the hand, was felt; an enema with the long tube was administered; vomiting of fæcal matter set in, but nothing passed from the intestines. The fæcal vomiting continued unchecked, as also the other symptoms, and the patient gradually sunk and died on the 14th.

Treatment.—He was leeched on the 9th inst., the pills of mercury and opium continued, and blisters dressed with mercurial ointment applied over the abdomen, and opium, in small doses, viz., gutt. xv. of vin opii was given every three hours; and brandy was administered.

I wish now to turn your attention to some points connected with the dissection. Cases like that before you being very likely to present themselves in practice, which, in the suddenness of their occurrence, naturally excite great sympathy and alarm. On turning aside the abdominal flaps and looking to the pelvic region, all the small intestines lying in it were seen coated with lymph, and a quantity of plastic lymph lay through them in all directions, moulding itself through their interstices; the viscera, as they lay in situ, both in the true and false pelvis, being covered with layers of the same lymph. Passing to the right iliac region, the cæcum was observed to be distended with air, and covered also with layers of lymph, which were in some portions from a quarter to half an inch thick, and in the flexures between the ileum and caput coli was a deposition of lymph, so thick as to form the solid tumour that had been felt during life. The cæcum was adherent by a very thick layer of lymph to the peritoneum, in raising off which numerous bloody dots were observable. As the viscera were traced up along the right side as high as the liver, they were found covered with lymph mixed with sero-purulent fluid. The pelvic intestines, it should be remarked, were also slightly distended; I would here draw your attention to the line of demarcation which bounded these pathological conditions. As the large intestine was traced up from the cæcum, it was found, after a few inches, to lose all trace of inflammatory action, and all the ascending, transverse, and descending portions of the colon were equally free from it. The sigmoid flexure was in a similarly healthy state; but the rectum was covered with the same lymphy layer which invested the small intestines. You are to observe, that the stomach, left lobe of the liver, the duodenum, and jejunum were all perfectly free; in fact, that all the regions constituting the left half of the abdomen down to the false pelvis were free from any lymphy deposition whatsoever; or, taking the opposite view, we find that the whole of the right side, commencing from the stomach and including the right lobe of the liver down to the ileo-cœcal valve, presented the diseased conditions just alluded to. The mucous membrane throughout the whole intestinal track, with the exception of the rectum, was perfectly healthy, not alone in the upper portion of it but even in that part of the ileum and colon in which lymph had been shed to nearly the depth of an inch. It had not the slightest appearance of disease.

Round the outside of the caput coli, into which the ileum projects, there was the deposition of lymph already described, but no mechanical obstruction whatever existed. The disease might in the first instance have been, and probably was, an attack of intussusception of the ileo-cœcal valve into the caput coli, but all trace of this had disappeared. There was, as I have just said, no mechanical obstruction whatever, in proof of which, observe this important fact, that there was a quantity of healthy fæcal matter, of a pasty consistence, not only in the ileum, but a considerable amount of the same material scattered along the course of the colon. If, at the point of projection of the ileum into the cæcum, inflammation ever had gone far there was yet no disease produced, and the deposition of lymph around the cæcum, though communicating to the finger a solid feeling when pressed deeply, had not been productive of any obstruction. Yet the patient had iliac vomiting and obstinate constipation. It is at the point of projection of the ileum, you are aware, that intussusception most frequently takes place, and, probably, irritation at that point gave rise to the peritoneal inflammation; however, he was, on the fifth day of his illness, free from all uneasiness; could bear pressure down to the back bone, when on that day, the 4th of March, drinking whiskey caused a relapse.

Let us now seek for an explanation of the symptoms presented during life. The parietes over the diseased parts felt tense and as if distended by something beneath. The muscles ceased to exert their contractile action over the inflamed viscera of the abdomen: nature, as it were, endeavoured to relieve the parts from pressure. This was very remarkable in this case, when the parietes covering the pelvic and right iliac regions were examined, and was particularly well illustrated in a case of peritonitis admitted to the Hardwicke Hospital some days since, in which, on feeling the right side, where the disease was, the sensation communicated to the hand was as if distended intestines were felt through a fold of inelastic cloth.

We come now to the consideration of particular points, and first let us inquire what the cause of the constipation is in the disease before us, and what its treatment. But, digressing just for a moment, I would remind you of what I said about this man having got a relapse from not having given himself fair play. For it illustrates an occurence very frequent in practice. It often happens that persons just after recovery, subject themselves to relapses from the imprudent use of stimulants, excesses in food, or taking purgatives; nothing is more common than for a return of the disease to prove fatal, under circumstances of this kind merely exciting the peristaltic motion of the intestines will prove sufficient, just upon the same principle, that a man lately recovered from an attack of pleuritis would, by exercising the intercostal muscles in blowing a wind instrument, produce a return of the disease. Anything, in fine, that will produce excited action, or cause an attrition of the serous surfaces against each other, may give rise to a relapse. Motion should be avoided, here, in fact, with as much care as in an inflamed joint. But to return to the question of constipation and iliac vomiting—what gave rise to the obstinate constipation, and what is the treatment proper for you to adopt, suppose a similar case presents itself.

The ideas entertained about constipation, previously to the publication of Abercrombie's work, were

* We have to apologise to Dr. Corrigan, as well as to our numerous readers, for the long period during which we have been compelled to postpone the [illegible] lecture. It has been in type fully one [illegible], and has been delayed only in consequence of the great length of Mr. Guthrie's lectures, which [illegible] publish as they are delivered.

associated with the existence, merely, of obstruction in the intestinal canal, in the removal of which the recovery from an attack of peritonitis was sought for. At a time when post-mortem examinations were not as frequent, or as carefully attended to, as they now are, such an inference naturally suggested itself at first sight, and it was consequently deemed expedient to purge and procure free evacuations; but we now know that violent peritonitis is very often connected with a free discharge from the bowels. To Abercrombie and others we are indebted for the knowledge of the fact, first strikingly brought forward by the former, that obstinate constipation may be present without any mechanical obstruction whatever, and that this is not the less true, whether peritonitis be or be not present.

A question which naturally suggests itself to us is, whether does the constipation in these cases and so strongly marked in the case before us, exist as cause or effect?—for upon this, our treatment depends. Now, when upon the most careful examination of the whole canal, we find its upper portion, including the stomach, duodenum and jejunum, all healthy with the exception of some slight distention with air; when we find the ileum filled with pasty fæcal matter, and the same in the cœcum and remainder of the colon, and that neither by injection or any other means did the intestine act, or any portion of the contents of these several divisions of it, advance along the tube in the slightest degree, though no obstruction existed; viewing, I say, this one case alone, even without the information given us by Abercrombie, we must inevitably come to the conclusion, that the case is purely one of peritonitis, and that the peritonitis is the cause of the obstinate constipation. Recollect that all the intestines in the pelvis were covered with plastic lymph, that the cœcum was in a similar condition. Coupling, therefore, all the facts above detailed, you cannot, I think, come to any other conclusion, than that the case before you was one of peritonitis engaging the whole of the small intestines, which inflammation acting on the muscular tissue in contact with the inflamed serous membrane, interfered with the peristaltic action of the affected portion of the intestinal canal, which was thereby rendered unable to pass its contents onwards. To this circumstance is the fæcal vomiting to be attributed, and the constipation likewise. We know it to be a fact in pathological physiology, that there is an instinctive effort to keep at rest an inflamed part; you see it, as I before said, in the intercostal muscles; in pleuritis you see it in an inflamed joint. If then, you come to the conclusion I have advocated and I think that uniting reason with the facts detailed, you can draw no other practical inference—it follows that your treatment is not to be directed to efforts for overcoming constipation by the administration of acrid purgatives.

Relieve the serous inflammation, and permit the peristaltic action of the intestines to return, but do not force it; look upon the constipation as effect, not as cause. Taking the case in another point of view, of what harm is the presence of pasty fæcal matter in the intestine productive? We know it to be unirritating in its effects in the bowels of the child; surely it cannot, then, be the cause of such mighty mischief as to require removal by the administration of croton oil and such like drastic purgatives. Let the first object be, therefore, to look upon inflammation as the cause of the constipation in peritonitis, and to endeavour to remove it by the application of leeches, by blistering, and putting your patient under the influence of mercury; and recollect what I told you of the danger of a relapse from the use of stimulants of any kind. While we lay down these principles as our guide in treatment, it is not necessary—if I may use a vulgar phrase—to ride a hobby. Where accumulations occur in the colon, their removal may be advantageously obtained by the introduction once or twice of the long tube, as recommended by Dr. O'Beirne; but it is worse than useless to repeat this process after, and so attempt to force a discharge of the contents of the intestine. Suppose a man labouring under pleurisy opened, what would you think of the person who would force the intercostal muscles of the affected side into action, and cause a rubbing together of the two sides of the inflamed membrane? Again, fancy the abdomen of a patient, affected with peritonitis, exposed to your view, with the cœcum and small intestines intensely inflamed, and that while nature was doing her best to keep these parts in a state of rest, croton oil was thrown into the intestinal tube by one inlet and stimulant injections through another. Surely such would be an error of practice perceptible to the commonest capacity. Pay no attention, then, to the unirritating pasty fæcal matter lying in the intestines beyond the injection recommended above, but direct all your faculties to the subduing the existing inflammation by leeches, bleeding, blistering, and the administration of mercury. I could relate to you several cases in which this plan was attended with the best success where the purgative plan had previously been ineffectual and injurious; but I find I have already gone my hour.

The Structure and Functions of the Brain,

WITH NEW VIEWS ON

THE NATURE, CAUSES, AND TREATMENT OF MENTAL DISEASES.

By M. PINEL, M.D., Member of the Academy of Medicine, formerly Physician to the Bicêtre and Salpetrière Asylums, Author of the "Traité Médico-Philosophique sur l'Aliénation Mentale," "Medicine Clinique," "Nosographie Philosophique," &c. &c. Translated, with Notes, illustrative of some important Doctrines in Physiology, Phrenology and Moral Education,

BY DR. COSTELLO,
Principal of Wyke House Asylum, Editor of the Cyclopædia of Practical Surgery, &c.

From the preceding cases of general paralysis, or, to speak more strictly, of paralytic cerebritis, which exhibit the disease in its various forms, we may now proceed to make a few reflections on its general anatomy, symptoms, seat, and treatment.

When its progress is the most rapid, it is characterised by an inflammatory turgescence of the whole periphery of the brain, more particularly of the grey substance; the corpora striata share also in the inflammation, and even the whole substance is highly congested, though for too short a time to allow of the disorganisation becoming perceptible.

In the chronic form, which is the most common, the same alterations are found, but of a more decided character; the grey substance softened, ecchymosed, peeling off with the membranes to which it adheres in many cases, presents erosions, mottlings of colour, general thickening, and slight layers of albuminous exudation; the white substance is also altered, being bluish, soft, sometimes ecchymosed, yellowish, and no longer presenting the fibrous character of health. All these alterations are found in the atrophy of the brain, and this atrophy depends obviously on the chronic inflammation of the cerebral pulp, and differs widely from senile atrophy, or from that which results from hæmorrhage. In the latter cases the void is filled by serum, by a cyst, or by false membranes containing the remains of the unabsorbed blood. In the atrophy arising from paralytic cerebritis, the convolutions shrink, and seem flattened against each other, and the anfractuosities disappear, the cerebral hemisphere is considerably reduced, there is a void between the skull and brain, and the membranes are collapsed upon it.

This atrophy pervades the whole of the convolutions, or only a few, but is observed in the frontal, middle, and posterior regions.

The hypertrophy of the white substance must be regarded in paralytic cerebritis as an inflammatory turgescence, which augments the density, as well as the bulk, of all its parts; it seems to develop itself from the basis towards the periphery by a gradual extension until it finally forces and flattens the convolutions against the skull. Blood-vessels can no longer be discovered in it, and the induration extends at last to the annular protuberance. These lesions are frequent in a chronic form amongst epileptics.

Symptoms.—Whatever the cerebral alteration may be, the first symptoms are a general difficulty of speech and deglutition, slight disturbance of the ideas, generally partaking of the character of exaggeration. Such usually is the beginning of paralytic cerebritis, to which the medical man should give his best attention, and which will enable him to prognosticate a mortal malady in a person who still seems full of strength and health. In a little time feebleness of the lower extremities, alternating with evanescent exaltation of their movements, is observed.

The second stage is characterised by the greatest intensity of the symptoms; the paralysis extends to the upper limbs, the patient can no longer use his arms, or he clutches convulsively whatever he tries to hold in his hands; the general sensibility grows obtuse, the excretions involuntary, and at last the muscles of the intestinal canal itself become involved.

The third stage is marked by the aggravation of all these symptoms, by the commencement of marasm, and the formation of gangrenous eschars. Sensibility and intellect are almost abolished, contraction of the limbs and partial convulsions supervene, with complications in the thoracic or abdominal organs, and the patients expire in the most advanced state of marasm; but it often happens that they are carried off by some sudden congestion in the second stage of the disease.

Seat.—General paralysis being charcterised by a lesion of motility, in strict reasoning, we must look for its seat in the motory nervous centres and fasciculi, and as these motory fasciculi are expanded throughout a large portion of the hemispheres, this arrangement would of itself suffice to explain the influence of the cerebral alterations above described on the production of the phenomena of paralysis. But in this disease there are other peculiar lesions of motility that demand a more rigorous explanation. It is observed that the first that manifest symptoms of paralysis are the muscles of the tongue, pharynx, œsophagus, diaphragm, and the sphincter of the anus and bladder, and that it is only after these that the inferior extremities first, and then the superior, are involved. We entertain no doubt that this disease begins with lesion of the corpora olivaria, or of the nervous fasciculi proceeding from them; or if the disease begins in the periphery of the brain, that it must involve some fasciculus, or some nervous tract in connection with those bodies. We have a right to suppose that, from their singular conformation, the nucleus of grey substance that forms their centres, their development in man alone, the corpora olivaria whose functions are still a problem, must preside over some faculty peculiar to man, such as the articulation of laryngeal sounds, the emission of the voice; and that, moreover, the nerves of the pharynx, larynx, and tongue arise from the olivary fasciculi, and that it is the lesion of those organs that specially reveals the general paralysis; that the facial nerve also arises from the same source, and that the trembling of the lips and checks of the paralytic are also very remarkable; that, according to Bell, the olivary fasciculi are destined for respiration, as the pneumogastric derives its source chiefly from them; that we remark in these patients inertness of the diaphragm, slow respiration, an asphyxiating languor of certain inspirations, and slowness of the heart's pulsations; that the lesion of the pneumogastric nerve would account for all these symptoms as well as for the paralysis of the sphincters of the anus and bladder.

The identity of seat in such varied alterations as we find not only in cerebral paralysis, but in epilepsy, and other nervous affections of the intellect, sensibility, and motility, cannot be accounted for in sound cerebral physiology, by any other means than that of a constant lesion of some nervous tract, fasciculus, or centre, specially destined to intellectual, motory, or sensitive functions.

But as those tracts, fasciculi, and centres are found expanded throughout the totality of the cerebral hemispheres by means of planes of fibres, whose direction, relations, and connections are still a subject of uncertainty even for the anatomist, it follows that the cerebral mass, which is the special organ of the intellectual and moral acts, becomes by its very structure the seat of the lesions in all their variety of the motory and sensitive functions. Hence it follows, also, that its alterations, however slight, or however profound,

will give rise to phenomena in which the intellect, motility, and sensibility will be disturbed singly, or altogether, chronically or acutely, according as the lesion involves more or less particularly one or more of those fibrous plans, or as the progress of the affection is more or less rapid.

In general paralysis, the pathological anatomy of which embraces that of all the other diseases of the brain, the identity of symptoms proceeds necessarily from the constant lesion of the fibres, or tracts which are connected with the corpora olivaria, whatever besides be the portion of the hemispheres that may be attacked. We believe that, when the paralysis precedes the disorder of the intellect, the disease begins directly in the olivaria, and, on the other hand, when it begins by demency, that the alteration extends from the brain to the motory tracts in connection with the olivaria, and that it is then we have the symptoms of general paralysis first manifested.

For the rest, the alterations of the corpora olivaria are as well characterised as those of the nervous centres, only the examination of them is wholly neglected in autopsies, and possibly even on account of the difficulty of appreciating them. Some observers, amongst others Guislain and Esquirol, have noticed their state of induration in epileptics. In general paralysis their appearance and size are constantly in relation to the appearance and size of the white and grey substances of the brain. In the atrophy of the cerebral convolutions we find scarcely any vestige of grey substance in the olivaria. In hypertrophy their yellow bands are thickened and swollen, and their prominence is more or less knotted and firm. We entertain no doubt that, in the stutterers and the dumb from birth, the olivaria moreover offer alterations still more characterised.

Treatment.—We have tried, for the cure of this disease, everything that a tolerably intimate knowledge of its nature, and a sincere wish to be useful, could suggest; blisters on the head, cold affusions prolonged for a considerable time, blisters to the neck, setons to the nucha and along the spine: externally, we have employed all known derivatives; internally, all the medicines reputed anti-paralytic; drastics, which we think highly dangerous; tonics combined with antispasmodics; yet we cannot affirm that any of these means produced a satisfactory effect. True it is that some intervals of amendment, some moments when the symptoms seemed to be stopped or to improve, have been observed; but soon again the disease gained ground with renewed intensity. What are we to do against a chronic inflammation that slowly disorganises the convolutions, that then penetrates deeply into the interior of each cerebral lobe, and that is shielded from any direct action by the protection of the skull itself? What are we to attempt against a medullary hypertrophy progressing acutely, and in which the activity of increase seems to arise from the superabundance of the capillary circulation? What against those sudden and repeated congestions which, in a few moments, asphyxiates the little that remains of healthy brain, carrying off these paralytics as if they were struck with lightning? Take blood from them, and they die of a decomposition rendered only still more rapid; produce a derivative action on the bowels, and they perish from enteritis, the effects of which cannot be arrested. At certain stages of the disease even sinapisms give rise to gangrenous eschars on the places they are applied to.

One fact is very striking in the amidst of these incertitudes, namely, that patients attacked with general paralysis, who are nursed at home, and who have the means of obtaining constant attention, changing their linen and bedding as often as it may be necessary, live much longer than those who are crowded together in hospitals. In this respect the ground floor wards of the Paris hospitals are the worst of those establishments; the wards in particular in which paralytics in an advanced stage of the disease are placed have a typhoid and cadaverous aspect, which soon shows itself on their half-disorganised bodies, and this case is so far instructive in showing that hygienic attentions form the chief part of the treatment. The point most important and most urgent is to place each patient in a well-aired room; to have his linen changed whenever it becomes wetted or soiled; to prevent his being long confined to one position, either in bed or chair; to make him walk now and then; and keep him continually clean.

As to the direct treatment, two principal indications are offered—to unload the brain on the one hand, and to support the patient's strength on the other. The best means to secure the first we have found in the application of scarification and cupping on the nucha every day for months, taking care each time to take but little blood, at most half a spoonful, while the food should be tonic and substantial. Although these indications seem contradictory, experience has shown the good effects of the practice, especially in private practice, when we have been called in the early stage of the disease. We have always found bleedings, abstinence, and a debilitating regimen, to accelerate the progress and aggravate the symptoms. It must not be inferred that all the other means usually employed are to be rejected; they ought to be varied to meet particular indications. We only mean to point out those which seem to have produced the best effect.

As to the causes of paralytic cerebritis, we have only ascertained three of them with any degree of certainty, the first is the abuse of alcoholic liquors, next grief and distress, and lastly hereditary predisposition, which represents alone all the causes in this disease, as well as in all others.

II.

HEMIPLEGIC AND PARAPLEGIC PARALYSIS.

In our view paralysis is a symptom of a lesion more or less profound of some nerve or fasciculus, of some centre of the cerebro-spinal apparatus; it consists in the diminution or complete abolition of motion and sensation in the limbs, or in certain parts of the body; it is complete when both are abolished at the same time, and incomplete only when one of these properties is affected.

There are, however, some remarkable instances of muscular paralysis, in which the sensibility acquires an extreme degree of susceptibility; in such cases it may be supposed that the motory cords are already disorganised, while the sensitive cords are still in the stage of irritative exaltation.

It has been said that certain substances, absorbed into the economy, have the property of determining paralysis, such as lead and its preparations, the effect of which is to abolish motility in the lower limbs. Their action is characterised by a soporous state, weight in the head, and headach, from which it might be supposed that these preparations cause congestion of certain parts of the brain for the time, instead of acting directly on the muscular fibre of the limbs. The paralysis may affect a single region, a few muscles, or only one muscle; the functional lesion is always relative to the material and determining lesion; strabismus, the paralysis of the eyelids, of the muscles of the face, of a limb, or of a few fingers only, are those most frequently met with singly. Hemiplegia, or the paralysis of half the body, is the most frequent of all; paraplegia, the paralysis confined to the lower extremities, is the more rare.

The treatment of paralysis rests wholly on that of the organic causes that gives rise to it. The reader will refer to those causes, the most serious of which are apoplexy, inflammatory or senile softening, congestion of the brain, and all acute or chronic inflammations of the brain.

III.

DELIRIUM TREMENS.—ALCOHOLIC DELIRIUM.

In the disease so well described by Rayer under the name of delirium tremens, we have not only disorder of the intellect, but also of the motility. In our view this affection is but the first stage of what we have observed in general paralysis, only that its determining cause being alcohol, the symptoms disappear as soon as the patients are put on abstinence and proper treatment. On this point I have only to repeat that the most frequent cause of general paralysis is the abuse of alcoholic liquors; persons in a furious state are often brought to Bicêtre, presenting the symptoms of general paralysis from habitual excess in drinking; they soon get well again, while others pass into the state of confirmed general paralysis. And thus alcoholic delirium is the most fatal predisposition to paralytic cerebritis.

Another species of paralysis may be observed at the Salpêtrière in young women who have undergone mercurial treatment several times—a kind of mercurial delirium or paralysis. In large doses mercury disorganises the brain, and produces all the symptoms that announce the beginning of general paralysis and of alcoholic delirium. I have seen several fatal examples of this kind.

Alcoholic delirium, the madness of drunkards, always arises from the habitual and prolonged abuse of spirituous drinks, and is characterised by disorder of the intellect, embarrassment of speech, sleeplessness, and trembling of the limbs. This affection supervenes almost always suddenly in the midst of health: the patients are attacked with an intense delirium, which does not completely overthrow the intellectual faculties; the delirium is at one time hilarious, affectionate, and loquacious; at another furious, with vociferations, shouts, and invectives. With the delirium we have usually trembling of the upper limbs, sudden shocks in the arms and wrists, flushing and injection of the face and eyes. The duration of the attack is generally short, and its termination favourable; but when the cerebral congestion is very great, coma, and sometimes a true inflammation of the brain, supervene.

The treatment is simple, consisting in the administration of opium; the emission of blood is injurious in the first stage, and must not be had recourse to unless imperatively demanded by the violence of the congestion. Andral gives 100 drops of the laudanum of Rousseau in the space of an hour; under the influence of this dose the patient falls into a profound sleep for ten or twelve hours, and awakes in perfect health. The form under which opium is administered, however, is not of much importance, being equally successful almost in whatever mode it is administered.

IV.

TREMBLING.

Trembling of the limbs, whether local or general, is a lesion of motility we often meet with; in old people, it frequently depends on atrophy of the posterior convolutions of the brain: in the young it may arise from masturbation, vivid emotion, anger, or fright. It has been observed to arise from abuse of coffee, tea, or opium, or from mercurial vapour, or from preparations of lead.

The trembling may be confined to the head, an arm, a hand, and may occur while the person is at rest or in motion, periodically or continuously.

The most frequent seat of the continuous chronic trembling must also be in the roots of the motory nerves corresponding to the limbs; and hence we must act on the vertebral column by means of derivatives, the action of which should be gradually increased. In mercurial trembling, milk diet, tepid baths, purgatives, and sudorifics, with vapour baths, are prescribed. Sulphurous baths have also been found useful in nervous trembling.

A Course of Lectures on Diseases of the Skin.

By JAMES STARTIN, Esq., Surgeon to the London Cutaneous Institution.

LECTURE X.

LICHEN ET STROPHULUS.

According to Willan, and others.

GENERA.	SPECIES.
Lichen.	L. Simplex Pilaris Circumscriptus Agrius Lividus Tropicus Urticatus
Strophulus	S. Intertinctus Albidus Confertus. Volaticus Candidus

As proposed by Startin.

GENERA AND SPECIES.	DIVISIONS.	VARIETIES.
LICHEN ET STROPHULUS.		
L. Simplex vel papulatus		
Agrius	Localis.	Sparsus.
Lividus		Confertus.
Urticatus		Circumscriptus
Tropicus	Generalis.	Inveteratus
Infantilis vel strophulus		

To a disease of the skin closely approximating in its more advanced stages to eczema, when about to become chronic, Willan has given the name of lichen. This careful writer, however, has considered the disease named by him lichen to be entirely confined to adults, in order that it might not be confounded with the disease occurring in infants and young persons, which he has named strophulus—a circumstance that otherwise would have been of constant occurrence, as the maladies are undoubtedly identical; the different vascularity of the skin in the two ages being sufficient to account for any variations which exist in their appearance.

In consequence of this discrepancy, several writers, who have followed Willan, have changed or modified the definition "lichen." Yet, with a few exceptions (that of Rayer in his Traité Theorique et Pratique des Mal. de la Peau. vol i, p. 360, being the most decided), they have not united lichen and strophulus under one description I must, therefore, beg, you will consider that the next in the series for our consideration, or that known as strophulus, is comprehended in the description, and forms the variety I have ventured to name lichen infantilis. I shall follow the definition of Rayer rather than that of Willan, who in all former instances has furnished the groundwork of the characteristics I have given to the affections brought before you.

Lichen may be defined to consist in a non-contagious inflammation of the skin (the papillæ being chiefly affected), often attended by constitutional disturbance, and manifested by a simultaneous or successive eruption of deep red, or flesh-coloured pimples (papillæ), which may appear scattered or in groups, on one region, or over the entire surface of the body. These papillæ contain neither lymph, nor pus, effused in a circumscribed cavity, but terminate naturally, or, from the irritation and friction to which they are subjected, in a furfuraceous desquamation; or more rarely by troublesome superficial excoriations, imperfectly covered with thin crusts, which the microscope determines to be composed of lymph and blood discs, very irregularly intermixed.

Lichen was divided by Willan into five varieties, to which Bateman added two others, viz., L. simplex, L. pilaris, L. circumscriptus, L. agrius, L. lividus, L. tropicus, L. urticatus. These seven species are named either from arrangement, colour, severity, or the influence of climate on the eruption, with the exception of the last, which is a complication with urticaria. This is so frequent an occurrence in lichen that I have considered it one of the usual forms in which the disease is manifested, You observe by this tabular chart, that I have dealt with lichen as with the affections hitherto considered. by arranging it under certain species, which, in compliance with already created nomenclature, are termed, L. papulatus vel simplex, L. agrius, L. infantilis vel strophulus, L. lividus, L. urticatus, and L. tropicus, whilst the divisions of the disease are local and general, and the forms consist of sparsus, confertus, pilaris, circumscriptus, and inveteratus.

There is, perhaps, no chronic disease of the skin which is so frequently preceded or attended by the constitutional symptoms of fever and irritation in the chylopoietic viscera as lichen. A familiar example of this is to be found in the infantile process of dentition, which is constantly attended with a lichenous eruption, commonly known as the red gum, the strophulus of Willan, and L. infantilis of this lecture.

Lichen occasionally appears without any indisti on, and shows itself for the most part amongst the poor and ill fed. All ranks, ages, and conditions, however, are subject to its attacks; and under the designation of prickly heat, L. tropicus, few inhabitants of northern countries can reside for any time in tropical climates without experiencing its attacks, as I myself can testify, having in one instance, at Cette, in the South of France, been visited by it for a short period. At first I mistook the papules for mosquito bites, but soon found from my friend, Dr. Daniel, resident there, that it was a well-known torment in that locality. In my case it arose from bathing in the sun on the shores of the Mediterranean, where as much as one to two hundred yards of shoal water must be passed before you can reach a swimming depth. The size of the pimples in lichen does not exceed that of a large pin's-head; they are mostly, however, more conical in shape, and, as mentioned in the definition I have given you, contain neither pus or serum, their consistence being solid, and their colour redder than the healthy integument. When the epidermis covering these papulæ is abraded, or they are opened with a sharp instrument, a little bloody serum exudes, which does not escape from a cavity, but from the torn or divided vessels of the part. The duration of each pimple is not commonly more than a week or ten days, but others constantly appear, so that the complaint may last for months, or years; atmospheric change, errors in diet, constitutional derangements, or mental disquietudes, for the most part materially influence the severity of this eruption, whilst they more or less modify its form, whether it be papular, livid, or joined with nettle rash; it may be well, however, to give a brief description of each species before proceeding to point out the divisions and forms of the complaint. The symptoms I have hitherto detailed refer almost exclusively to the simple or papular form, of which the next species, L. agrius, is but a chronic variety, which may, perhaps, be better considered under the form inveteratus. The next two species, L. lividus and L. urticatus, are in reality complications of lichen, with other diseases of the skin, the former being in combination with purpura, the latter with urticaria; thus, L. lividus, in addition to the symptoms characterising L. simplex before detailed, is more or less attended with petechiæ intermingled with papulæ, presenting a deep red, or livid hue, the arms and legs being the regions most commonly affected, though in protracted cases the complaint extends to the other parts of the body. This eruption is most frequent in sickly persons. It is a very rare affection, and I have not seen it more than three or four times amongst the patients attending this institution, which would make it occur about once in 1800 cases of skin disease. The lichen urticatus is a comparatively common form of the complaint, and usually manifests itself after some constitutional irritation; it is most common in children, and then perfectly answers to Willan's definition of strophulus candidus. The pimples constituting this lichen are more irregular in form than those of L. simplex or papulatus, and more closely resemble the bites of insects, appearing often in clusters or patches; yet they are found intermingled with true lichenous papulæ. This lichen is more common on the neck, trunk, and face, than on the extremities, and though most usual in young subjects, is not infrequent in adult or old age, when it becomes a matter of some difficulty to distinguish it from prurigo, as will be seen hereafter. Much itching and tingling accompany the affection.

L. tropicus, known in warm climates as prickly heat, or in Italy by the term pellagra, comprehends all or any of the symptoms mentioned as appertaining to the former species, or to the forms I shall presently describe, which become modified, augmented, and excited by the temperature of tropical climates; the papulæ are accompanied by a more violent pruritus, and often cover the whole body, which then becomes the seat of the most intolerable irritation, inducing the sufferer to tear his skin, so as to produce ulcerations and excoriations, which are very difficult of cure, unless a removal to a milder region can be accomplished; yet I have often seen sailors and others thus affected on their return from India and elsewhere, when their disease has perfectly resembled what I have said of L. agrius, and shall say of the inveterate forms of lichen.

The last remaining species of this disease on the chart, which I shall notice, is exemplified by the models from children, and termed lichen infantilis, the strophulus of Willan and his followers. This species has precisely the same identity with the different varieties of lichen in adult life, that psoriasis infantilis exhibits with that complaint, when occurring in mature age; the greater vascularity and irritability of the skin in infancy, determining the only visible difference, and the more usual exciting cause being the irritation of dentition, or improper feeding and want of cleanliness.

This rash, well known by the popular name of red gum, very commonly disappears when the infant has completed his first set of teeth; but it commonly continues to a greater or less degree after its first appearance, notwithstanding curative efforts, until the above process is accomplished. The varieties of strophulus, as mentioned by writers, entirely correspond with the divisions I have named of lichen, but they are of a brighter red tint, being accompanied by more or less surrounding inflammatory blush: thus the S. intertinctus, S. albidus, and S. volaticus, answer to the description given of L. simplex sparsus; and the S. confertus, with L. confertus, whilst S. candidus is to be referred to L. urticatus.

We will now take a cursory glance at the different forms of lichen, the first which I have called sparsus, consists in a scattered or diffused distribution of papulæ, and it may occur in union with any species of the complaint; it is, perhaps, the most usual manner in which lichen appears.

The second form, confertus, differs only from the preceding, in the papulæ being grouped or collected together, into spots or patches, instead of being spread irregularly over the surface of the affected portion of the body; these patches are prone to heal in the centre, and spread by the circumference; occasionally, also, the healing process commences on one side of the circular patches, whilst the opposite border extends; thus bands and irregular figures are formed, as in psoriasis gyrata, into which, as into the other varieties of psoriasis, this form of lichen occasionally seems to merge.

The third form, L. pilaris, differs only from the L. simplex sparsus, in the circumstance of the papulæ being developed on those eminences of the skin which give exit to the hairs, to the bulbs of which the inflammation of the disease often extends itself; so that this variety of lichen commonly affects the skin more deeply than those hitherto mentioned.

The fourth form, circumscriptus, may comprehend any of the foregoing manifestations in a circumscribed spot; such lichenous patches are very common, and often would seem to be a sort of plaything for the patient, who amuses himself with scratching them in his leisure hours, and thus continues a complaint, which would often disappear of itself if undisturbed.

The last form the different species of lichen may assume I have termed inveteratus, which, as I have already observed, is more commonly an attendant upon the species Willan has designated agrius. When this is the case the disease shows itself by a confluent eruption of papulæ, of a bright red colour, arising from an inflamed surface, accompanied by more or less constitutional disturbance, and attended by sensations of burning heat and insupportable irritation, which are much increased at night from the warmth of the bed; the complaint in this form is an absolute torture. When this severe form of lichen arrives at its chronic stage, the skin assumes a harsh, dry, and rough aspect, and is divided by deep furrows covered with a furfuraceous secretion.

As might be expected, much constitutional disturbance attends L. inveteratus, as demonstrated by pains in the epigastrium, in the region of the liver, vomiting, diarrhœa, and other disorders of the digestive organs.

The duration of this complaint may extend to nearly the whole life, and the patient finds but a temporary relief from his sufferings from any of our remedies.

The causes of lichen must be sought for amongst those already cited, as producing other eruptions of the skin; gastro-intestinal inflammatory affections, and hepatic derangements, being more constantly found to precede or attend lichenous diseases, than other maladies of the skin. Heat of weather, or sudden atmospheric changes, influence these eruptions in a very marked manner, and the return of hot weather, or a particular season, is often the signal for a periodic visitation of lichen, in any of its forms or varieties; this is particularly the case in persons of irritable constitution and high nervous development, who, besides, seem most liable to the complaint. Indeed, mental emotions of any kind, in such parties, are not unfrequently followed by an eruption of lichen. The most usual complications of lichen are psoriasis, impetigo, eczema, and urticaria, the latter being so frequently witnessed as to constitute a recognised form of the disease L. urticatus. I have also found it attend L. lividus, when it would come under the designation of purpura urticans of Willan; the connection of lichen with pemphigus is also called pompholyx pruriginosus by the same author.

I have never seen lichen appear as a critical eruption, though it has been considered the scabies critica of authors; yet, I think its external appearance very constantly relieves internal disorder of long standing in cases where such a symptom has been pre-existing; and I have witnessed such complaints alternate, the internal manifesting itself on the disappearance of the external, and vice versa. Lichen and its varieties present so many anomalous appearances, that they are apt to be confounded with other cutaneous complaints, particularly scabies and eczema; but the absence of a cavity in the papulæ, filled with lymph or pus, and the anatomical portion of the dermis occupied by the malady, will at once establish our diagnosis, for instance, as lichen has its seat in the papillæ of the dermis, the situation it occupies on the outer and posterior parts of the members, will distinguish it from scabies or eczema, which follow the distribution of the cutaneous follicles, and therefore are seen more commonly in the flexures of the joints, and on the internal surfaces of the limbs. In addition to which, sulphur and its compounds very constantly produce irritation, and aggravate lichen, whilst they have a curative effect on these diseases; a circumstance that may often usefully be borne in recollection, when determining this disease. There is more difficulty in discriminating between lichen and prurigo; but the absence of redness or inflammation in the latter complaint, for the most part affords a sufficient means for diagnosis.

With regard to the prognosis of lichen and its varieties, this will much depend upon the cause and duration of the complaint; if it be recent and may be supposed to originate from the heat of the weather, a fortnight or three weeks' regulation of the diet, and the daily exhibition of sulphate of magnesia in the acidulated infusion of roses, will suffice for its removal; but, on the other hand, should the complaint have become chronic, it may last for months and years, and require a gentle mercurial course and external stimulants for its cure; the great torment occasioned by this complaint in otherwise healthy individuals, and the incessant friction to which they subject the affected parts, tend much not only to aggravate, but also to prolong the disease. It is scarcely possible to conceive a greater degree of misery and irritation arising from any complaint of the skin, than from lichen in its severe or inveterate forms, which also seem only alleviated by a long perseverance in any remedies which can be employed; though, for the most part, they may be ultimately moderated by venesection, and active purgation, with the use of tepid mucilaginous, or gelatinous baths, and a strictly regulated diet, confined to milk and boiled meats, all stimulants being excluded; and when thus subdued, a cure may sometimes be accomplished by frictions with mercurial ointment over the diseased parts, until the constitution is slightly brought under the influence of the mineral.

In the less severe forms, for which a cause is not readily traced, the cold bath at the atmospheric temperature, or the shower bath, has often proved useful, whilst the mineral acids in a vegetable bitter, or the decoction of bark, either with or without saline purgatives, have been found efficient remedies; the system of counter-irritation requires very skilful and careful management in cases of lichen; yet creosote, trisnitrate of bismuth, biniodide of mercury, &c., may be occasionally used with success, when the disease is not in one of its numerous exacerbations, in which case local or general bleeding may be called for, and iodine and colchicum indicated.

Every case of chronic lichen will, however, require careful study, that not only its cause may be discovered and removed, but also that our remedies may be adapted to its particular stage or condition, as well as to any peculiarity in the constitution of the patient. But, Gentlemen, I sh... endeavour to elucidate this part of my subject, the treatment of lichen, more completely in the cases which at our next meeting I shall bring to your notice, and as several interesting examples of this disease are now in attendance at the Institution particularly one of that rare form Willan has named L. lividus; I shall obtain the personal attendance of these parties, so that you will not only have an opportunity of verifying what I have said by the models prepared for your inspection, but by the manifestations of Nature herself, which after our best efforts have been exerted, still furnishes the examples that may best guide us in the complex study of cutaneous diseases.

A PRIZE ESSAY ON PURULENT ABSORPTION.

Communicated to the MEDICAL TIMES by THOMAS OTTLEY RAYNER, M.D., F.S.A., &c.

(Continued from page 18.)

The experiments I have detailed are imperfect, because, in the first, the matter injected was not nearly of the consistence as pus; in the second, the dog survived too short a time to allow any marked effects to develope themselves. Nevertheless, their results, together with the other considerations I have mentioned, justify the conclusion that the irritation produced by pus, if merely mechanical, is, at least, of a very violent kind; and a strong opinion that in many cases, pus, in contact with living tissues, excites inflammation having a specific tendency to terminate in the effusion of more pus. The question in its various bearings is one of great interest, and deserves special investigation, of which I hope one day to make it the subject.

We have seen, from the cases and experiments which I have cited in different parts of this essay, that consecutive abscesses show a marked preference for certain organs and textures, viz., the lungs, the liver, and the joints, and afterwards in order of frequency for the spleen and the muscles. How are these facts to be explained?

When we consider that all the blood of the system, and consequently all matters mingled with that blood, must necessarily in each round of the circulation pass through the lungs; that a very large proportion of the blood passes equally often through the liver, and moreover, that, from the peculiar manner in which this organ receives its blood, and from the size and multitude of its capillaries, the circulation through it is very slow, the solution of the question, as far as it regards these two organs, becomes obvious.

The experiment of Cruveilhier, of injecting mercury into the veins, confirm the view here indicated; for, when thrown into the general venous system, the greater part of it was always found scattered through the lungs; but, when into the portal system by means of a knuckle of intestine drawn out through an incision in the abdomen, it was found equally disseminated through the substance of the liver. It is no objection to the inference deducible from these facts, that the pus supplied by phlebitis of a vein that empties itself into the general system, and is, therefore, carried first to the lungs, frequently causes abscesses of the liver also, because Cruveilhier found that, in some of his experiments, many of the mercurial globules were carried *through* the lungs, and were afterwards arrested at different points of their passage through the general system. An observation made by Andral (Essai d'Hem. Path.) also bears upon this point; in a case of disseminated abscesses following a large psoas abscess, he found upon examination with the microscope that the blood of both ventricles of the heart contained pus globules, but that they were much more numerous in the right ventricle than in the left.

It has also been found, by examination of numerous cases in which phlebitis of some of the veins of the portal system has been the cause of death, that abscesses in the liver were the only consecutive lesions produced. A case of this kind is reported by Cruveilhier, in which such abscesses followed violent and repeated efforts to reduce a prolapsus ani; and another has lately been mentioned to me by Mr. Partridge, in which they were caused by the operation for fistula in ano. The lungs and liver, therefore, appear to act as filters, retaining a large number of the pus globules during their passage through them. The liver appears to accomplish this more completely than the lung, on account probably of the less force of the circulation through it, and the complicated nature of its capillary network; that in consequence of the large quantity of blood which passes through them, more pus corpuscles are arrested in these than in any other organs; the necessary result of which is that they become the most frequent seats of consecutive abscesses. But the joints, the spleen, and the muscles, suffer in the next degree of frequency. Can we account for this? A knowledge of the anatomical peculiarities of these organs will, I think, furnish the explanation.

The recent researches of Mr. Toynbee on non-vascular animal tissues, lead to proving that these tissues, the chief of which is cartilage, are nourished by the exudation of the nutrient liquor sanguinis from the vessels in their vicinity, which in consequence, the venous capillaries especially, are very numerous and large; those of the bone, in immediate contact with the articular lamella, form dilatations capable of holding a large quantity of blood, which, therefore, circulates very slowly through them. Those of the synovial membrane and the areolar tissue in its vicinity, serve the same purpose, and accordingly exhibit similar peculiarities. It is evident, from this statement, that if the views concerning the primary seat of the inflammation caused by pus, expressed in a former part of this paper, be correct, that these large sinuses, from the slowness of the circulation through them, and consequent accumulation of the pus corpuscles within them, must be very liable to become inflamed. The bones forming a suppurated joint must also in most cases be purulent in their interior, but I have never met with a case in which this point has been examined into. Such an examination would be very interesting, and should the result I anticipate be established, it would afford a strong confirmation of the above supposition. It is no valid objection to this view that the eye does not often become the seat of an abscess consecutive to ordinary phlebitis, because, though the vessels which nourish the extra-vascular tissues of this organ are numerous, and some of them large, they do not exhibit the remarkable ampullæ formed by the veins which supply cartilage. In puerperal fever—a disease very analogous to plebitis, which, indeed, constitutes the principal lesion in many of its forms—the eye-ball very frequently suppurates.

We may account for the frequency of consecutive abscesses in the substance of muscle in a similar manner. The vessels supplying it are very numerous, and two large veins accompany each artery to within one or two gradations of the capillaries themselves. The great vascularity of the spleen indicates the reason why it so often becomes affected.

But can we account in any way for the concentration of the inflammation in patches, so that circumscribed abscesses always result? The question is a very difficult one; the following, however, appears to me a probable answer. Pus mingled with the circulating blood must, when carried to the lungs, be diffused pretty equally

throughout those organs; but, nevertheless, it is easy to conceive that a greater number of corpuscles may be carried to one or two capillary veins together, than to others, and consequently the disturbance of the circulation in them would be more complete than in their neighbours.

According to recent observers, the first stage of inflammation consists in enlargement of the vessels in which it takes place, and consequent slower motion of the blood within them, just as we see in a mountain river, which at one part contracts itself into a rapid stream, at another deepens and widens into a pool, in which the current is very slow. The blood circulating, therefore, more slowly in such vessels, the pus globules would accumulate in them more and more at each round of the circulation, and inflammation would be thus determined in such spots, while the rapidity of the circulation through the surrounding vessels would be increased, and the chance of pus corpuscles being arrested in them diminished. Suppuration in one joint rather than another in different cases, must be determined by similar accidental circumstances.

I am quite unable at present to account for the lower lobes of the lungs being always more extensively affected than the upper ones, or for the preference which disseminated abscesses exhibit for the surface of these organs. A similar preference for the surface being shown in the liver also, indicates that it depends principally on some peculiarity in the mechanism of the circulation. In the early part of this essay I endeavoured to prove that in all the cases in which disseminated abscesses following a primary lesion had been discovered, such primary lesion either was actually found to be, or else from its nature and situation was very likely to be complicated with purulent phlebitis. It would appear from this that phlebitis is the only disease in which infection of the blood by pus, in quantities sufficient to cause consecutive abscesses, takes place. Some pathologists, however, have recorded the opinion that pus globules exist in the blood in a number of diseases.

Mr. Gulliver, for instance, in a paper published in the *Phil. Mag.*, September, 1838, announced that he had discovered with the microscope pus globules in considerable numbers, in the blood of patients labouring under erysipelas, small pox, consumption, hectic from chronic abscesses, &c. Mr. Lane, in a letter to the *Medical Gazette*, shortly afterwards, confirmed this statement; and I find that Andral, in his recent Essai d'Hem. Path., also says that he has seen pus globules in the blood in similar diseases, marked by characters so decided as to admit of no doubt about their nature. Now these statements would, if true, go far to invalidate the theory which it has been my object in this essay to establish, because we do not find disseminated abscesses common in such diseases. I believe them, however, to be erroneous, for the following reasons:—

1. Because in all inflammatory states of the system, the lymph or colourless corpuscles of the blood have been found to increase greatly in number, and to become larger than those observed in the healthy state; in this condition they have so much the appearance of pus corpuscles, that it is almost impossible to distinguish one from the other. With the kind assistance of Mr. Bowman, I have examined under his microscope, various specimens of blood taken from patients suffering from several of the diseases mentioned by Mr. Gulliver. The following are a few of the results:—

1. Blood taken from the right ventricle of a dog who died from the injection of pus into the veins. Examined forty-eight hours, p.m. Pus globules very abundant.

2. Blood taken after death from the arm of a man who had died of sweep's cancer. Many lymph globules, with small granules like those found in pus.

3. Blood from a vein in the back of a patient with vomicæ in the lungs. Lymph globules more abundant than natural.

4. Blood from child with lumbar abscess. Rather more lymph globules than healthy blood.

5. Blood from an erysipelatous foot. The same result. The lymph globules observed in many such instances presented no characters sufficient to distinguish them with precision from the pus corpuscles contained in the blood in the first instance mentioned.

2. The recent researches of Mr. Addison, and more especially those of Professor Gerber, tend to show that reparation is effected by means of these lymph or exudation corpuscles, which are thrown out upon an injured surface, and become organised in the form of the particular tissue to be repaired; that, when inflammation runs high, these are produced in too great abundance; that the supernumerary ones apparently die, and are thrown off from the inflamed surface in the form of pus corpuscles; that this result never takes place in an internal organ till inflammation has gone so far as to produce disorganisation; and that it is no more possible for pus produced in such situations to get into the circulation, than it is for pus thrown out upon an external surface to find its way unaltered into the blood.

I conclude, therefore, that the corpuscles seen by Gulliver, Lane, and Andral, were lymph corpuscles, and that pus in quantities sufficient to cause disseminated abscesses, never enters the circulation, except in cases complicated by phlebitis.

It is no objection to this conclusion that disseminated abscesses have been found without any phlebitis being detected. 1. Because the examination is incomplete and, therefore, invalid, unless all the large veins, as well as the interior of the bones, are inspected. 2 Because the local appearances of a phlebitis, the pus from which it has caused disseminated abscesses, may disappear before the death of the patient from the latter lesion.

By some it has been objected to the theory I have endeavoured to sustain, that we every day see large abscesses disappear by absorption of the pus they contain into the general system, yet no disseminated deposits follow; but the objection betrays ignorance of the known laws of physiology, which point out the possibility of the absorption of substances in solution only: indeed it is absurd to suppose that a solid body like the pus corpuscle can pass unaltered through the equally solid walls of the absorbent vessel. That pus is often absorbed is true, but before it can be so, the pus corpuscles must undergo some change, probably solution, after which it is taken up, and then excreted by the proper emanations. Sometimes it is left behind in the form of cheesy matter.

Suppuration in the lymphatics seldom or never gives rise to consecutive abscesses, because the matter is arrested in the lymphatic glands, to which it is necessarily first conveyed; these appear to act as filters to the pus, and to prevent the solid parts of it from passing into the circulation.

The question has been suggested, Are any other of the products of inflammation besides pus, capable of causing consecutive abscesses? The only experiment that I am aware of, bearing upon this point, is one performed by Magendie, who caused consecutive abscesses in the joints of a dog by injecting into its veins ten ounces of the serum of the blood of another dog. It would seem, therefore, that serum and flakes of lymph probably, if carried into the circulation in large quantities, may cause such disturbance in the capillaries as to terminate in suppuration. But considering the readiness with which effused serum is absorbed, the large quantity necessary to produce the effect, and the fact that when a sufficient examination has been made pus has almost always been found the exciting cause in the human subject, I imagine that the production of abscesses by any other means must; in nature, be very rare.

CASE OF PUERPERAL CONVULSIONS.

By D. Watkins, Esq., London.

Mrs. Rawlings, aged twenty-six, of a sanguine temperament. This is her fifth accouchement; had gone her full time, and was attended and delivered by a midwife, ten, p.m., March 29, 1846. The fœtus and placenta were expelled naturally, and the labour was a remarkably easy one. During the period of utero-gestation she suffered occasionally from several attacks of headache, and this pain continued, with slight intermissions, until after delivery, when it gradually increased; during the night she complained of giddiness. At twelve, meridian, fourteen hours after delivery, headach increased, and was accompanied by a fit of vomiting, soon followed by strong convulsions.

Half-past one, p m. I first saw the case. The symptoms were of a distressing character: the mouth drawn to one side; the breathing laborious and quick, each expiration characterised with the puffing or bellows-noise so constantly noticed in apoplexy; a gurgling noise in the throat; skin hot, and profusely perspiring; the pulse full and rapid; the head hot, and the carotids beating violently; the pupils contracted, and unconscious of the presence of light; the paroxysms appearing about every eight minutes.

Venæsectio. ℥ xx, statim.

℞. Hydr. chloridi, gr. v, statim sumend.

A bladder with ice applied to the head; Empl. lyttæ nuchæ, and mustard poultices applied to the calves of the legs and soles of the feet.

The convulsive paroxysms at first came on every eight or ten minutes, but after the bleeding, &c., the intervals became gradually longer, and they entirely disappeared about half-past three, p.m. A violent state of restlessness supervened, which again was followed by a drowsy stage, interrupted frequently with slight fits of delirium.

Five, p.m. By rousing, she shows some symptoms of returning consciousness. Dr. Lever arrived at this stage. Extractio urinæ, which was slightly albuminous; highly acid

℞. Ol. terebinth, Ol. ricini, āā ℥ j; Dec. avenæ, ℥ xx; fit. enema statim inject.

℞. Ant. pot. tart., gr. iss; Magn. sulphatis, ℥ ss; Liq. ammon. acet., ℥ iss; Aquæ ad. ℥ vi; capt. coct. duo larg. 4tis horis.

Ten, p.m. Has less headach; has slept soundly; restlessness nearly gone; skin moist; pulse low; bowels not relieved.

Rept. dosis misturæ 2dis horis.

One, a.m. Bowels opened; brain relieved, and talks perfectly rationally; complains of uterine pains; the lochial discharge established; thirsty, and slight headache.

Perstet in usu medicinæ.

March 31. Has passed most part of the night in sound sleep; still complains of slight headach and thirst; bowels have been freely opened. Infant put to the breast.

Perstet. in usu medicinæ.

April 1. Feels comfortable; headach and thirst gone; tongue moist and clean

Ten, p.m. Going on well; no bad symptom.

ON ALBUMINURIA.

By Dr. George Gregory.*

"Almost all the diseases which have hitherto come under review are characterised by a symptom, or group of symptoms, easily cognizable during life, and often as obvious to the casual observer as to the experienced physician. Small-pox, measles, jaundice, apoplexy, consumption, and diabetes, afford familiar illustrations; but we have now to investigate a disease which depends on the lesion of a deep-seated internal organ, and whose chief feature is only to be detected during life, by careful study and accurate chemical research. Such a complaint is by no means uncommon, and must doubtless have occurred to the observation of the older authors. Many cases of this disease were described by them under the general appellation of *dropsy*. Some were designated, with even less of scientific accuracy, by the term *decay of nature*.

"Dr. Bright, in 1827, having first directed the attention of physicians to this subject, the disorder has been sometimes called *Bright's disease*, and the peculiar disorganisation of the kidney, on which it depends, *Bright's kidney*. More recently, the albuminous condition of the urine has been con-

* Extracted from the sixth edition (just published) of Dr. Gregory's admirable work on the "Practice of Medicine"—a volume which we can conscientiously commend to a place on the library table of every one of our readers.

sidered as the most important, because the most frequent, and the most easily cognizable, among the symptoms of the malady; and the term albuminuria has been proposed and very generally adopted as its pathological designation. In diabetes the urine is loaded with sugar. Here the urine is almost uniformly impregnated with albumen, that animal principle coagulable by heat, which is so familiar to us in the white of eggs. But a variety of other symptoms are present also. We have therefore to investigate these, to point out under what conditions of the general system albuminuria occurs, from what causes it originates, with what disorganisations it is associated, to what extent it affects life, and how its advances may be most effectually controlled. The labours of contemporary writers have thrown much light on these interesting objects of research.

"*Symptoms of Albuminuria.*—The affection so designated may, like rheumatism or pneumonia, show itself in an acute or in a chronic form. The acute form is ushered in by rigors, succeeded by a hot skin, nausea and vomiting, uneasiness, or a dull pain in the loins, with a scanty secretion of albuminous urine. In almost all cases, general anasarca appears at the same time, of that kind which has been already described, (p. 251) under the title of inflammatory, active, or arterial dropsy. In a few cases the secretion of urine, after a few days, is suspended altogether, when comatose symptoms supervene, and death speedily ensues. At other times, the inflammatory action extends to some other internal organ, and the patient dies from the results of peracute pleurisy, pericarditis, pneumonia, or peritonitis. Occasionally the strength of the patient's constitution, aided by the vigorous efforts of the physician, overcomes the disease, and perfect recovery succeeds. In a certain proportion of cases recovery is only partial, and a foundation is laid for that more chronic ailment which indicates the granular degeneration of the kidney, and to which the term Bright's disease is commonly applied.

"The kidneys, when examined after death so occurring, appear larger than natural, of a dark or chocolate colour, and evidently gorged with blood. The other viscera present appearances which may be generally anticipated from the character of the symptoms during life. Whether the gorged condition of the kidney, and the albuminous state of the urine, are the primary and more essential features of the disease, or only incidents in the series of phenomena, are points still open for discussion. It has been already stated, when treating of anasarca, that this acute malady admits of essential relief by general bloodletting. Cupping glasses applied to the loins, active purgatives, saline diuretics, and the antiphlogistic diet and regimen, are here obviously indicated.

"*Chronic Albuminuria.*—The leading feature of this disease is the voiding of a highly albuminous urine of low specific gravity. The concomitant symptoms have, for the most part, very little reference to the kidney, and are only to be connected with it by a process of reasoning. The patient often complains of a weight in the loins. The bladder is irritable, and there is a frequent desire to make water. The urine is occasionally red, or dark coloured, as well as albuminous, and sometimes tinged with blood. The countenance is pale; the skin dry and harsh. Vomiting is sometimes observed. The bowels are flatulent and irregular, and the liver is frequently suspected to be the primary seat of mischief. Patients labouring under this disease are liable to inflammatory and congestive states of other important organs. Hence, in its progress, coma, convulsions, and apoplexy may occur. The heart, too, may become implicated, and dropsy is almost always met with sooner or later.

"It will be observed that these symptoms have no very direct or obvious reference to the renal affection; and it is far from improbable that the advance of science may detect some more general condition of the frame, to which all the phenomena now enumerated are referable. In the meantime the albuminous condition of the urine observed during life, and the disorganisation of the kidney detected after death, are the points which specially merit our attention.

"*State of the Urine.*—The urine in this disease is always of very low specific gravity, never exceeding 1012, and sometimes falling as low as 1004. Now the specific gravity of healthy urine is about 1015, and in diabetes mellitus it often rises to 1040. This unnaturally low density of the urine in albuminuria, notwithstanding the addition of the new material, shows that the other ingredients proper to healthy urine (the urea and salts) are preternaturally diminished in quantity. The solid contents of healthy urine amount to about seventy parts in a thousand. In this disease they are often reduced to twelve, and I have been met with even lower than this.

"The quantity of *albuminous* matter in the urine varies in different cases, and in the same case at different periods of the disease. It does not necessarily increase with the advance of the disease, but rather the reverse. In general, the albumen is most plentiful in its early stages. The presence of albumen in the urine is readily detected by the simple experiment of heating the urine in an iron spoon over the flame of a candle. An additional test is the application of nitric acid, which has the property of precipitating albumen in a flaky form. This is especially applicable when the suspected urine is preternaturally alkaline, and the albuminous matter thereby rendered less sensible to the action of heat.

"Healthy urine contains no albumen. This animal principle is the great agent in nutrition, and is not an excrementitious product. We might reasonably presume, therefore, that the urine in this disease obtains its albumen at the expense of the serum of the blood. Experiment confirms this opinion. It has been ascertained, by Dr Christison and others, that the more the urine is loaded with albumen the less of it there is in the serum of the blood, and the lower is the specific gravity of the serum. Another remarkable change which the blood undergoes is the rapid disappearance of its red particles, or colouring matter. It is remarked by Dr Christison, that no disease so closely approaches hemorrhage in its power of impoverishing the blood and exhausting its red particles as albuminuria. Hence arises the peculiar hue of the patient's skin, and that waxy or leuco-phlegmatic aspect which so strongly characterises the victims of this complaint.

"In the early stages of the chronic form of albuminuria, the urine is generally scanty. Instead of the two pints which are commonly discharged in health, the quantity seldom exceeds one pint, and is often less than half a pint. In the more advanced periods of the disease, the quantity of the urine approaches more nearly the standard of health. In some few cases it has been found even to exceed it.

"*Renal Dropsy.*—Before proceeding to notice the morbid condition of the kidney so generally associated with an albuminous state of the urine, it will be useful to describe what pathologists now consider as the secondary effects of chronic albuminuria. They are of the same general nature as those already noticed as succeeding to the acute form of the disease. Foremost in the train stands dropsy, especially anasarca. The diagnosis of renal dropsy from that which is mainly dependent upon cardiac or hepatic disease is not easy. The skill of the physician is here tried to the utmost, and at times the most experienced pathologist may be deceived. The circumstances that chiefly direct his judgment, as to the presence of renal dropsy, are the following: —1. A very low specific gravity of the urine, more especially if, with diminished density, there be present also diuresis, and an albuminous condition of the urine. 2. The complexion of the patient. In the cardiac variety of dropsy, the countenance is often dusky and inclined to purple. In that which depends on hepatic disease, a yellowish tinge of the conjunctiva is generally perceptible. In the true renal dropsy there is a leucophlegmasia, or sallowness, very expressive of chronic disorganisation. 3. The previous history of the patient, the apparent causes of the disease, and the absence of symptoms indicative of cardiac or hepatic disorganisation. To this it may be added, that ascites and hydrothorax are less common in renal than in cardiac disease. But as cardiac and renal disease may, and often do, co-exist, there are obviously many occasions when the diagnosis is impossible.

"The other complications or secondary affections concurrent with albuminuria, are headache, lethargy, epileptic fits, coma, and occasionally complete apoplexy. Dr. Christison is inclined to view coma as the normal mode by which this disease proves fatal. Serum is in such cases usually found in the ventricles of the brain, and to the pressure thence arising, the comatose state may reasonably be attributed. Some pathologists contend, that urea retained in the blood may act as a poison to the nervous system, and in this manner give rise to the succeeding apoplexy. Of seventy fatal cases observed by Dr Bright, death was ushered in by well-marked cerebral symptoms in thirty.

"The complication of renal with cardiac disease affords some curious matter of speculation. Dr. Bright records the particulars of a hundred cases, in twenty-seven of which no affection of the heart could be detected. Hypertrophy was the most frequent condition of cardiac disease observed in the remaining cases. Whether in this combination the cardiac disorganisation is to be considered as dependent on the renal,—whether it advances *pari passu* with it,—or, lastly, whether renal disease be ever produced by the cardiac, are questions in pathology not yet satisfactorily determined. An hypertrophied heart is doubtless calculated to occasion congestion of the viscera, but albuminous urine is not a necessary concomitant of cardiac disease.

"*Morbid Appearances.*—There is considerable variety in the appearances described by authors under the generic title *Bright's kidney*. The surface of the diseased gland is generally mottled or speckled with uneven projections. In some instances it is quite rough and scabrous. The size and consistence of the kidney are equally liable to vary. In the early periods of the disease it may be found larger than natural, and of softer consistence; in the advanced stages, contracted in bulk, and hard. When cut into, it will be found that the outer or cortical portion of the organ is the chief seat of disorganisation. It is granular, and generally of a pale-yellow colour, well described by Dr. Watson as presenting the aspect of a cut parsnip. The medullary structure of the kidney is seldom much altered. In the most aggravated forms of the disorder, the tubular portions of the gland are almost entirely absorbed, while the infundibula and pelvis are dilated. The renal veins have been noticed as firmly plugged up by coagula of blood.

"*Causes of Albuminuria.*—This disease prevails at different ages, and under apparently very opposite conditions of the general system. It has been met with in infancy. In 1838, a boy between five and six years old, anasarcous, and passing bloody and albuminous urine, was under the care of Dr. Wilson, at the Middlesex Hospital in London. The dropsy which succeeds scarlet fever is often associated with an albuminous condition of the urine, and granular degeneration of the kidney. The chief subjects of the disorder, however, adults in the prime of life. Men are more liable to it than women. The scrofulous habit of body seems to give a tendency to it. Intemperate habits undoubtedly favour the disposition to this degeneration of the urinary apparatus. Exposure to cold and moisture have been noticed as one of its direct exciting causes. It has sometimes appeared to originate in injuries to the loins.

"*Prognosis.*—The ample manner in which morbid anatomy has determined the pathological connexion between albuminous urine and granular degeneration of the kidney, is alone sufficient to show the very dangerous nature of the malady. Dr. Watson has known a few instances of what seemed to be complete recovery after well-marked symptoms of albuminuria, but he acknowledges that the disease is prone to recur.

"*Treatment.*—The remedies specially adapted to the albuminous condition of the urine have not hitherto been determined with the accuracy which is desirable. The pain and tenderness of the loins, so often present, suggest the propriety of relieving the tension of [illegible] by cupping glasses, but general bloodletting is contra-indicated by the exhausting tendency of the disease, when it occurs in its chronic form. The dropsical accumulation must be removed, as far as possible, by purgatives and diuretics. The secretions of the skin are to be

encouraged by the use of warm baths and diaphoretics. Dr. Osborne remarks, that when the renal affection is uncomplicated with other organic mischief, the dropsy will disappear on restoring the functions of the skin. Opinions vary as to the propriety of employing mercury in the granular degeneration of the kidney. Instances of recovery are recorded after severe salivation, but the general impression is, that the mercurial influence is prejudicial rather than salutary. It is not improbable that more enlarged experience will unfold some remedy peculiarly appropriate to the treatment of albuminuria. The natural tendency of so many drugs to pass off by the kidney, and to influence its secretion, holds out great encouragement to attempt a more effectual treatment of this disorder than any which has been yet devised."

HOSPITAL REPORTS.

MEDICAL TIMES PRIZE CASES.

SECOND SERIES.

Reported by THOMAS FRANCIS I'ANSON, of St. George's Hospital.

MEDICAL CASES.

CASE I.—*Case of Phthisis with Pneumonia.*

Emma Wilson, aged twenty-four, cook, was admitted June 4th, by Dr. J. A. Wilson. Bowels irregular; urine high coloured; tongue clean; catamenia regular; evident dyspnœa. She complains of extreme weakness, with shortness of breath, and a sense of tightness across the chest, without, however, any actual pain in that part. She has also sore throat, which causes difficulty in swallowing, and slight inconvenience in speaking. From the medical man who attended her previous to her admission, we learned that about six weeks ago she suffered from a severe attack of pneumonia, which caused the lower parts of both lungs to become quite dull on percussion, and almost impervious to air; that crepitation had gradually but only partially returned; and that she had since remained in an extremely debilitated state. On questioning her she stated that she had never been very strong; that about Christmas last she caught a cold with sore throat; since that time she had not been perfectly well, for she had frequent hacking cough with a little frothy expectoration; and on running up stairs she had experienced shortness of breath, and any unusual exertion had soon fatigued her; that on one occasion she had spit up a little red blood; she had also perspired greatly at night and her bowels were sometimes very much relaxed. Since the attack she has not been able to breathe unless propped up in bed, and her nights have been very restless from coughing. She has blue irides, dilated pupils, and a clear skin, with the superficial veins clearly seen.

June 6. On making a physical examination of her chest, general motion of the ribs was evidently diminished, but there was no particular depression in the infra-clavicular regions. On applying the hand there was found to be increased vibration on speaking and coughing. Percussion gave a short, dull sound over the whole of both lungs, which was not much increased on inspiration, either in duration or clearness. On applying the stethoscope respiration was heard to be quick, but with the expiratory sound comparatively prolonged, and louder than natural; towards the apices of the lungs it was distinctly tubular; it was not at all jerking; here and there a sub-crepitant ronchus could be heard on taking a full inspiration; bronchophony and bronchial cough were very distinctly heard; the heart's action was also heard over a much larger space than natural. Under the clavicles a distinct murmur of the subclavian artery was heard; her tonsils were enlarged, and ragged from superficial ulceration, causing an abundant secretion of mucus.

Haust. nitri, Inf. cinchon., āā ℥vj bis die; Pulv. ip. c. gr. vj; Haust. potas. cit. ℥ss o. n.; Decoct. cinchon. ℥ vj; Tinct. myrrh.; Lin. ærugin, ā ℥ ss. ft. gargarisma; two eggs; milk, Oij; beef tea, Oj.

9. She has obtained more rest at night, her cough being more quiet; but the difficulty of breathing has decreased very little; her throat is in much the same state. She has had several liquid motions this morning.

Vin. rubri. ℥ ij, quotidie.

10. Complains of occasional catching pains in the left side during inspiration.

Cataplasm, sinapis lateri thoracis sinistro.

11. She appears very much worse this morning. Pain in side has increased; very great difficulty of breathing; pulse rapid and feeble; face blue; lips of a deep purple colour; pulse more rapid and feeble. Motions of chest more diminished, both on expansion and elevation. Crepitant ronchus may be heard nearly over the whole of the left side of the chest, especially during inspiration.

M. S. ad ℥viij; Haust. salin. ℥iss; Vin. ant. tart. m. xl 6tis horis.

She appeared to be more easy for a short time, after the bleeding, but gradually became delirious, and died in the night.

POST-MORTEM EXAMINATION THIRTY-SIX HOURS AFTER DEATH.

Thorax.—The left pleura was generally adherent throughout its whole surface by the effusion of recent lymph; the adhesions being easily separated. The right pleura was apparently healthy, and not adherent. Both lungs were filled throughout with miliary tubercles, some as small grey points; others, especially towards the apices, were larger and of a yellow colour; but none of them had approached the condition of softening. The left lung was also congested and inflamed, full of spumous fluid; its bronchi were also redder than natural. Heart apparently healthy; much coagula in right side; left side empty.

Abdomen.—Liver, spleen, and kidneys rather congested, otherwise healthy; much ulceration of the small intestines, with tubercular deposit in the seat of the ulcerations; and tubercles also found in the mesentery.

Larynx and Trachea.—Considerable superficial ulceration of the whole of the larynx, extending down the trachea; this had entirely destroyed the epiglottis, and a considerable portion of each tonsil.

I think, on viewing the phenomena of the present case, the most probable solution of it will be that, about Christmas last, from cold, or other cause inducing congestion within the lung, some slight deposit took place. I do not suppose that nearly so many tubercles could have been deposited there as were found at the post-mortem examination, or she could never have performed her common household duties, which she did, though with difficulty. But the difficulty itself was a sign of some obstruction; she also acknowledged having had slight hemoptysis—a further sign of obstruction in the vessels.

While in this condition she was attacked with pneumonia, either from some fresh exciting cause being applied, or from the irritation of the tubercles themselves. This, re-acting on the primary cause, gave rise to a fresh deposit, and left her with so little healthy lung that it was barely sufficient to aerate the blood slowly, and in small quantity. The second attack of pneumonia, though but slight, was sufficient instantly to turn the scale which before hung by so slender a thread.

For a correct view of the pathology of tubercles we are much indebted to Laennec, but still more so to Andral, and Carswell. According to their researches they are generally found to be small hard bodies, varying in size from that of a pin's head to that of a hemp seed, round, generally of a grey, and sometimes of a drab colour. They may be interspersed at considerable distances in a lung otherwise healthy; more frequently they are clustered together in groups, with the intervening structure consolidated; in some may be seen minute yellowish-white spots, which, when the granules are clustered together, often appear as a considerable white mass in the centre. Sometimes they occur as opaque, yellow, rounded masses, of a cheesy consistence, surrounded by indurated tissue; this appears to be formed out of the primary granules, where they have coalesced, though they may sometimes be found without any surrounding induration, as in the bronchial tubes, pleura, &c. Concerning the nature of these tubercles, Laennec considered that they were foreign bodies deposited in the lung, governed by their own inherent laws, independently of the tissue of the organ. Andral thought they were produced by chronic inflammation, causing induration of individual cells. The late Dr. Carswell, a most talented pathologist, supposed that the tubercular matter was secreted from the blood, along with the mucus of the air passages, and that it became set in this mucus, chiefly on the inner lining of the air cells. It might thus quite fill the cells, or only line the interior of the cavity, leaving the centre full of mucus; it was this which led Laennec into the error, that tubercles began to soften from their centre. It might also line the lesser bronchial tubes; these, when cut across, looking like rings of tubercular matter. This doctrine of Dr. Carswell's is held by most eminent men of the present day. Dr. C. J. B. Williams, however, appears to think that they arise in the interstitial texture, which becomes indurated in points, from a low and chronic inflammation; and he cites the instance of the pleura, which, when attacked by the same kind of inflammation, effuses lymph of low organisation, and fibro-cartilaginous structure. He says that these indurated points in the lung, being possessed of a low degree of vitality, throw into their centre a still less organic form of albuminous matter, which, pressing on the indurated matrix, causes its absorption; and thus is effected the conversion of the grey induration into crude tubercle.

Such are the separate views of two pathologists, but as this is a matter more of pathological than practical interest, and as none of the tubercles in the present case had passed on to softening, I shall pass at once to the *cause* of tubercles, which may be either local or constitutional.

The *local* causes are exemplified in persons who had enjoyed good health until attacked by some inflammation within the chest, which, being allowed to pass into the chronic form, lowers the vital powers, and leads to the deposition of albumen in degraded condition of a low degree, or perhaps devoid of organisation. Now, as lesions in this form may be confined to certain parts only, the cause being local, so we see that it is more tractable, and time is thus gained for the blood to accommodate itself to the diminished surface of the pulmonary apparatus; the existence of patients may be thus prolonged for years, with considerable comfort to themselves, so long as fresh causes of irritation are guarded against. Mechanical irritation will also induce this form, as in dry grinders, miners, and needle-pointers.

The most frequent *constitutional* cause is the existence of a scrofulous diathesis, in the large class who present this state of system, the blood is in an impoverished condition, and is greatly predisposed to deposit tubercular matter on the application of any slight exciting cause, whether it be imperfect nutrition, exposure to cold, unhealthy air, depressing mental emotions, profuse discharges, or the suppression of long continued ones, low fevers, chlorosis. I think that the disease in our patient may be safely said to arise from constitutional causes; she was evidently scrofulous, and owned to her system being easily impressed by slight causes.

The age of the patient may sometimes be looked on as a predisposing cause, for from twenty to thirty the growth is completed, but the blood and its vessels have not yet lost their habit of deposition. During this period the disease is most fatal, as found by Louis from statistical tables. He also found the average duration was from three to nine months.

The superior and posterior parts of the upper lobes are where tubercles are generally first deposited, and where they also first begin to soften. Dr. Williams thinks the reason of the upper lobes being more liable to deposit, is from the greater quantity of interstitial cellular tissue which they contain, aided also by the smaller capacity of of motion which they possess. Had softening commenced in our patient, it might have been the means of prolonging her life for some time, as it would have acted by bringing down the mass of circulating fluid to the lessened capacity

of the remaining lung. I must now pass on to the consideration of some of the phenomena of pneumonia.

On examining her body after death, the whole of the texture of the lung, which was not the seat of tubercular deposit, was found in a state of sanguineous congestion, or *engorgement* as it is termed. It was soft like the spleen, heavy, and on cutting into it a reddish frothy serum issued from it. This Dr. Williams believes to be generally the effect of the coagulation of blood after death; for when the blood remains fluid this is not observed. He believes also that the blood remains in the distended vessels, and in the tissues adjoining; but is not effused into the air cells, as is the common notion.

But we must suppose, from the account of her former medical man, that in her first attack the inflammation had proceeded further; in fact, that *hepatisation* had taken place. When this happens the lung presents a solidified appearance, resulting from the too abundant deposition of lymph in the tissues. It may be of a red, pink, or grey colour; but this is seldom uniform, for on making a section numerous minute granular points are observed, of a lighter colour than the rest; these were formerly thought to be air vesicles distended with mucus, but are now made out to result from the distension of the coats of the vesicles, from the interstitial deposit of lymph. This state is often recovered from, of which our patient is an example. But it often also passes into that of suppuration.

The other post-mortem appearances were what are constantly met with in phthisis, and may be set down as the effect of the scrofulous diathesis. Tubercles were found in the mesentery, also in the small intestines, where they had excited ulceration. The superficial ulceration of the larynx was what is often called laryngeal phthisis. Dr. Watson believes it to result from the irritation of the purulent secretion of softened tubercles; and says that when one lung only is diseased, the ulceration occupies only the corresponding side of the larynx. However, in this case it could not be from softened tubercle, as none of them had reached that stage. The vascularity of the bronchi, and pleuritic deposition of lymph were the effects of pneumonia; the inflammation spreading to the adjoining surfaces. I might further state with respect to the entrance to the air passages, that Louis has found the epiglottis ulcerated nearly as often as the larynx or trachea.

The history which was given of the complaint before the attack of pneumonia was such as usually occurs in the early stage of tubercular deposit. It commenced with slight cough, which is often regarded as the effect of a common cold, accompanied with clear frothy expectoration coming from the bronchi. She had had slight hæmoptysis; this is of very common occurrence. Louis found it in two-thirds of a number of phthisical patients, and more frequently in women; it may be either copious or inconsiderable. There was slight dyspnœa, only observed after exercise. She had little pain; this is of more frequent occurrence when pleuritic adhesions exist. Diarrhœa is of very frequent occurrence; out of 112 Louis had found it in all but five; it is the result of ulceration about the ileum and colon. Emaciation is observed in about one half the cases from the commencement; it had not happened with this patient, but I ought to have mentioned that the muscles were pale and flabby.

We had an opportunity of seeing the symptoms of the fresh attack of pneumonia, though they were of but short duration. We saw that it attacked one side only; more generally it attacks the opposite side, but we must suppose the existence of some strong irritation to determine it to the position which it occupied. There was sharp pain; this might be rendered more severe by the co-existing pleuritis. Dyspnœa was greatly increased. There was not much cough or expectoration; in fact, the powers of life were not equal to the efforts of coughing, and she died no doubt from the effects of the sputa accumulating in the air passages, and suffocating her (*i. e.* death by apnœa). Had the expectoration appeared, we should have found it to be a viscid, jelly-like mass of a tawny or rust colour, from the intimate admixture of blood. The delirium which occurred before her death showed that the aeration of the blood in the lungs was very materially interfered with, and caused the circulation of venous blood in the brain. She had, also, still further diminished motions of the chest; I presume that we might have heard the friction sound of pleuritis but for this circumstance. There was the characteristic minute crepitation; this proceeds from the smaller bronchi and air vesicles, and is generally believed to result from the rapid bursting of a number of small air bubbles. Dr. Williams, however, contends that the distended blood-vessels press on the smaller bronchi, which are lined with a thick viscid mucus, causing their sides to cohere, and that the air in passing separates the sides forcibly, and gives rise to the sound in question.

The general symptoms alone afforded strong grounds for the diagnosis of the early stage of tubercular deposit; the physical signs confirmed it. If we had had the opportunity of watching all the changes as they occurred in succession, from the commencement, we should have found (at least this is generally the case) that the deposits commenced in the apex of the lung, and by preference on the left side. The pneumonia, on the other hand, would have commenced in the lower lobes, and by preference on the right side. The existence of pneumonia on both sides was also a probable indication of the existence of tubercles.

The prognosis on her admission was quite unfavourable to the idea of her lasting for any long time; she had had a severe attack of pneumonia, which had excited tenfold the disposition to deposit tubercular matter; there was no vomica to assist in bringing down the mass of blood to suit the diminished capacity of the lungs; the night sweats and diarrhœa were natural attempts to effect that change, but they could not perform it with sufficient speed; the constant irritation in the lung again set up inflammation, and she died.

The treatment at first was entirely palliative: a light tonic, with Dover's powder at night, to procure her rest; and an astringent and slightly stimulant gargle to her throat. She took more liquid nourishment than would have been advisable had she been able to swallow solid food; this she was unable to do on account of her throat.

On the reappearance of the pneumonia a small quantity of blood was taken from her, and tartarised antimony given, with the view of emptying, in some measure, the distended vessels of the lung, and also of the head; such, however, was the violence of the attack that she soon sunk.

TRANSACTIONS OF LEARNED SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Meeting of April 28, 1846.

Dr. Chambers, F.R.S., K.C.H., President, in the Chair.

On the Capacity of the Lungs and on the Respiratory Movements, with the view of establishing a precise and easy Method of detecting Disease by the Spirometer. By John Hutchinson, Esq.; presented by Dr. Cursham.

After giving an introduction to the subject by a history of respiration from the earliest period to the present, with an account of the researches that have hitherto been instituted upon this inquiry, the author commenced by dividing the different portions of respired air under certain heads—without which the subject of respiration becomes very complicated and difficult of expression. He remarks:—"The latitude of movement performed by the walls and floor of the chest, to maintain a constant current of air through the air-cells of the lungs, admits of three common degrees of expression:—1. Extreme expansion or enlargement; 2. Extreme contraction or diminution; 3. An intermediate or quiescent state.

"These divisions necessarily superinduce a difference in the quantity of air respectively drawn in or thrown out of the lungs." These movements or portions of air he described, for perspicuity, under five heads:—

1. Residual air; 2. Reserve air; 3. Breathing air; 4. Complemental air; 5. Vital capacity.

This division was clearly illustrated by different diagrams, and may be expressed best in the author's own language:—

"It is well known that the lungs are not capable of being emptied by the most violent muscular effort; therefore at all times as long as the lungs maintain their natural structure during life or death, a certain quantity of air remains in these organs, which is termed 'residual air,' and over which we have no control."

"'*Reserve air.*'—The gentle respiratory movement regulating the ordinary breathing, is an intermediate effort between extreme voluntary thoracic contraction and dilatation, and hence it is that a portion of air always remains in the lungs after the gentle expiration, which may be thrown out if required: to it I have applied the name '*reserve air.*'"

3. Breathing air.—That portion required to perform the ordinary gentle inspiration and expiration, which we term "*breathing air.*"

4. Complemental air.—That portion which *can* at will be drawn into the lungs by a violent exertion, beyond the moderate effort of ordinary breathing, which constitutes the deepest possible inspiration, is only occasionally added if required; to this we apply the term "*complemental air.*"

"5. Vital capacity is all these three latter divisions combined, being the greatest voluntary expiration, following the deepest inspiration, to which I apply the term "*vital capacity.*"

These divisions differ in their character. The residual air is independent of the will and always in the chest. The reserve air, to use a simile, is a "*tenant at will.*" The breathing air constantly passing out of and into the chest. The complemental air—seldom in the chest—and when it is only so for a brief period.

The connection of these with diagnosis in disease here followed, and the whole subject of the paper resolved itself under the following heads.—1. The quantity of air expelled from the lungs in connection with other physical observations on the human frame; 2. The absolute capacity of the thorax, cubic and superficial measurements; 3. The respiratory movements and mobility of the chest; 4. The inspiratory and expiratory muscular power; 5. The elastic power of the ribs, and the voluntary muscular respiratory power; 6. The function of the intercostal muscles; 7. General and practical deductions in reference to detecting disease in man.

Each of these subjects were fully treated, and much valuable information both for the physician and the physiologist will be there found, but which we must here pass over and simply add, that Mr. Hutchinson has examined upwards of 2,000 cases with reference to respiration, and that the quantity of air exhaled from the lungs is affected by four circumstances—height, weight, age, and disease. By height in the arithmetic progression of eight cubic inches for every inch of height. By weight, nearly in the ratio of one cubic inch for every pound to eleven stone, and then a decrease nearly in the same ratio up to fourteen stone. By age (from thirty-five to sixty-five), a decrease of rather more than one cubic inch per year.

Under the second head much curious and new matter appeared in relation to the actual capacity of the thorax and the vital capacity, and the relative size of the chest to the body. Under the third head, the respiratory movements of the sexes, and relative movements in health and disease, as measured by the spirometer. Under the fourth head, the muscular power in relation to health. Under the fifth head, entirely new considerations of the combined forces of elastic or involuntary power, and muscular or voluntary respiratory power. Under the sixth head, the intercostal muscles being true expiratory muscles. Lastly, general and practical deductions.

Here Mr. Hutchinson gave many interesting cases of the spirometer detecting phthisis pulmonalis before the ordinary means now in vogue, and many other subjects relative to the application of his instrument to disease generally in the human frame, which he demonstrated as very broadly marked by twenty-five or thirty per cent.

Mr. Hutchinson, when the reading of the paper

was concluded, showed the method of making an examination of the capacity of the chest by means of the spirometer. He experimented first on himself, and showed that although his chest was small, thirty-three inches in circumference, yet his height indicated that his vital capacity was 260 cubic inches. The person while under examination should stand as erect as possible, the least bending of the head causing a corresponding difference in the quantity of air expired.

Mr. Hutchinson then invited any gentleman present to test the spirometer, and one of the members coming forward was first measured as to his height, which was found to be five feet five inches, and consequently the amount of air he should expel, if in health, would be, according to the tables, 206 cubic inches. The result proved that he expired 205 cubic inches—a very near approach to the amount indicated in the tables.

Dr. Taylor was of opinion that not only the Society, but the profession at large, were greatly indebted to Mr. Hutchinson for having carried out a series of such laborious investigations on a subject of so much importance. It was of course impossible, from merely having read an abstract of a paper embracing a variety of views possessed of great novelty, that their real value could be at once duly estimated. The paper itself must be read and studied before it could be fully appreciated. If the results at which Mr. Hutchinson had arrived should ultimately be proved to be correct, by the testimony of others, they would be of the greatest importance, but until they were confirmed due caution must be exercised in receiving them. Meanwhile, as far as Mr. Hutchinson could, he had guaranteed their trustworthiness, by the length of time he had devoted to the investigation, and the very large number of observations he had collected. He (Dr. Taylor) had som illy observed and repeated many of his (Mr. Hutchinson's) investigations, and could so far vouch for their accuracy. Some of the results obtained by Mr. Hutchinson were very singular, and they might serve to show how necessary it is in such a science as medicine, to be guided by observation alone; for although not at variance with admitted principles, still they were not such as would have been anticipated by *à priori* reasoning. Such, for example, is the rule which it appears Mr. Hutchinson has established, that the quantity of air expelled during the act of expiration is not in proportion to the circumference of the chest, but rather to the height of the individual. This is just the reverse of what would have been anticipated. One of the most interesting and important results obtained by Mr. Hutchinson is, that the height of an individual being given, the quantity of air in cubic inches which he should expire, providing his lungs are in a healthy state, may be calculated very closely. This rule is founded on very many observations, and was shown very fully by the gentleman who had kindly consented to test the spirometer, and who had breathed out air into the instrument to within one cubic inch of the calculated amount. The application of this principle to the investigation of disease is of great importance. Mr. Hutchinson, in the course of his inquiries, has ascertained that persons labouring under phthisis expel a much less quantity of air than they would have done in the full enjoyment of health. In the case of Freeman, the American giant, the quantity of air he expired previously to the invasion of disease was ascertained; some time afterwards, while in ill-health, but before two experienced auscultators could detect any physical signs of pulmonary affection, when again tested by the spirometer, he expelled about 90 cubic inches less air than before. The man ultimately died of phthisis. He (Dr. Taylor) had himself thus examined a number of consumptive patients, and had found that they expired much less air than they would have done if in health. This mode of physical investigation of the state of the chest, he thought, would prove of great importance in practice. It would appear that the quantity of air thus expired is not of necessity proportioned to the absolute size of the lungs or the capacity of the chest; for, from the casts exhibited by Mr. Hutchinson, it seems that one man who had expired a large quantity of air, had lungs which were much smaller than those of another man who expelled during expiration a much less quantity of air. The amount of air thus expired Mr. Hutchinson considers to be dependent on the degree of motility in the parietes of the thorax; and this is of importance in its application to disease, as the less amount of air expired by phthisical patients is not owing to the space occupied in the lungs by the tubercular deposit, but to the diminished motility of the chest. This fact complicates greatly the practical application of the instrument, as there are many diseases, both within and without the thoracic parietes, which may diminish their motility, and thus lessen the amount of air expired. At present, therefore, the diminution in the quantity of air expired, as indicated by the spirometer, can only be regarded as indicative of the presence of some disease, the nature and seat of which must be discovered by other modes of investigation. The result of Mr. Hutchinson's inquiries are such as to render it imperative on medical men to carry out his views by further investigation, and either confirm them, or render them invalid. A spirometer has been obtained for the hospital with which he (Dr. Taylor) is connected, and the results of the observations there made, as far as they go, tend to confirm Mr. Hutchinson's statements. An important recommendation of this instrument is the exceeding simplicity of its application. The physical examination of the chest requires close attention, and a prolonged education; but this instrument may be used for the purposes for which it is intended without much previous education. He (Dr. Taylor) therefore agreed with Mr. Hutchinson that the spirometer would be of great service to army and navy medical officers in testing the state of health of recruits, and to the life assurance offices in the examination of candidates for policies of insurance.

Dr. Alderson inquired of Mr. Hutchinson in what way he explained the movements of the abdominal muscles in deep inspiration, except by the descent of the diaphragm?

Mr. Hutchinson remarked that he had always observed that when a healthy man, standing upright, took a deep inspiration, the chest became enlarged, and almost entirely by the movements of the ribs; the sternum projected more, and the ribs and shoulders were elevated, the abdomen receding, and compressing the abdominal viscera. The enlargement of the chest was principally in the antero-posterior direction. He (Mr. Hutchinson) did not consider that the diaphragm could descend while the abdominal muscles were drawn in, and he thought it perfectly in accordance with physiology to admit that the diaphragm might enlarge its circumference without descending, its area being nearly quadruple that of the sectional area of the chest. In men the ordinary respiration was entirely effected by means of the diaphragm and abdominal muscles, but the reverse was the case in deep breathing. The chest may enlarge either by means of the diaphragm or by the ribs, but not by both consentaneously. When patients are lying down, the back becomes fixed, and the movements of respiration are altered, so that if the medical attendant examine a person when in bed, he may be led into error. The knowledge of this fact induced Mr. Hutchinson to attribute to it the ease derived from the sitting posture by patients labouring under dyspnœa. In women the ordinary respiration is more by the movements of the ribs than of the abdominal muscles, but whether this was from the effects of their dress, or to allow of the process of utero-gestation, he could not decide. He entertained, however, considerable doubt of the former cause.

Mr. Ayrton then inquired of Mr. Hutchinson what effects he had observed the previous habits of life exert on the capacity of the lungs, and the intensity of their action, in lifting the column of mercury, for instance, in the smaller instrument? Whether persons in the habit of using the lungs greatly, such as public singers or speakers, merely acquire a greater facility in expiring the air into the instrument, or whether they have, by their mode of life, increased the capacity of the lungs, or the intensity of their action?

Mr. Hutchinson in reply observed that the vital capacity increased with the height of the individual, but the respiratory power was at the maximum in persons averaging five feet eight inches in height, and decreased in gradual proportion as the individual exceeded that height. Persons five feet eight inches in height, being in a state of health, could by the action of the true respiratory muscles, raise a column of three inches of mercury, while persons who were six feet high could raise a column only two inches and a half high. The power of expiration was also one-third higher, but that was not dependent on muscular action, but on the elastic property of the ribs, which is not the case in the act of inspiration. The last-named act is one of direct muscular power, and he (Mr. Hutchinson) had given in the paper a series of tables illustrative of the alternate actions of the elastic property of the ribs, and the muscular action of the respiratory muscles in expiration and inspiration. The latter act, he thought, required the muscular power to resist the direct influence of the elastic power, amounting to many hundreds of pounds' weight.

Dr. Chowne inquired what explanation Mr. Hutchinson offered of the singular fact he had brought so prominently forward, that the absolute height of a person bore a direct relation to the vital capacity, which the size of the chest did not?

Mr. Hutchinson said that the relation was certainly singular, but it really was the case that the taller a person was, the more air would be expelled from the lungs by expiration, and he sought to explain the fact by referring it to the extent of motility of the thoracic and abdominal parietes, and not to the actual size of the cavity of the chest. He illustrated this remark by referring to some plaster casts of the chest, from which the lungs and heart had been previously removed. One of these, which he exhibited, had been taken from a man who, while in apparent health, had expired 251 cubic inches of air, while the actual space in the chest for the organs of respiration was only 248 cubic inches—three inches less than the amount of air actually expired. The motility is directly in proportion to the respiratory movements, which Mr. Hutchinson showed by drawings to extend over the whole trunk down to below the knees. Any interference, therefore, with the motility would be indicated by the spirometer, and then further investigation would show the part affected. It is generally believed that adhesion of the pleura interfered with the movements of the chest, but this, at all events, is not always the case; for, in the instance just alluded to, the motility exceeded the actual capacity of the thorax, although the two pleuræ were firmly adherent together, so much so that the heart and lungs could not be taken out of the chest without laceration of their structure. He (Mr. Hutchinson) thought that the lateral movements of the ribs, or between the contents of the chest and its boundaries, was so slight that adhesions could not interfere with the action of respiration. He then exhibited the cast of a chest which measured 457 cubic inches, while only 202 cubic inches of air were expelled. The man was corpulent, and only five feet, eight inches in height; there existed, therefore, a mechanical impediment to motility. He could not explain why this motility increased with the height of the individual; but he was certain of the fact, which was supported by upwards of two thousand cases. Mr. Hutchinson then drew attention to a table in which all the heights—increasing in the arithmetical rotation of inch by inch—from five to six feet, were drawn upon a scale, and opposite them were placed the relative depth and breadth of the chest. It showed that the size of the chest did not increase in proportion to the increase in height, but that, on the contrary, the taller men had generally smaller chests in every way than those who were shorter. The shallowness of the chest was also remarkable, the average depth from the apex of the lungs to the diaphragm being from seven inches and a-half to eight and a-half. The shortest man, who could expel the least quantity of air, had the deepest chest. He was only five feet, four inches in height.

A member asked Mr. Hutchinson if he had examined any dwarf with the spirometer?

Mr. Hutchinson had examined the dwarf, Don Francisco Santos, who is now being exhibited He had a vital capacity of 56 cubic inches. He had also examined a person who was seven feet high; the span of his hand was nearly thirteen inches, and the length of his foot thirteen inches and a-half. His vital capacity at 60° was 464 cubic inches,

which, if calculated at 98°, the temperature of the human body, would raise it to nearly 500 cubic inches.

SYDENHAM SOCIETY.

Anniversary Meeting, May 1st, 1846.

Dr. Paris, President, in the Chair.

The secretary read the report of the council, from which it appeared that the Society was evidently increasing in prosperity and success. Of the books issued during the first year, 1750 copies were issued, and since then 400 more have been printed; of the second year 2250 copies were printed, although at the time the number of members was not sufficient to justify the proceeding; but the Society has progressed to such an extent since, that the whole edition has been exhausted, and many applications for the volumes of that year have been, consequently, unsatisfied. Animal chemistry, it was then stated, was at present attracting so much attention, and was of itself a subject of such importance, that the council had readily adopted the offer made to them by Dr. Day to edit Simon's Animal Chemistry—a work which had obtained for the author an European reputation. The works of Paul of Ægina it was considered unnecessary to praise; they were also before the Society. The council felt great regret that so much delay had occurred in the publication of the works for the past year; it had been fully anticipated that a volume would have been ready for delivery in the autumn. An apology was also made for certain errors and irregularities which had occurred in the transmission of the volumes to the members, which, it was said, was in part owing to the frequent removals and errors in the addresses of the members. It was also intimated that a fourth volume for the year 1845-46 would shortly be published. In the last report, it was announced that the works of Dr. William Hunter would constitute one of the publications of the Society, but the sub-committee, to whom these matters are referred, had reported that it would not be desirable to undertake them, and consequently the intention was abandoned. The complete medical bibliography, also proposed at that meeting, was so far in progress, that a correspondence had been opened with several continental scholars, with a view to ascertain the degree of assistance that might be counted on in carrying out that object. It had been the intention of the council to issue Harvey's works during the past year, but it could not be completed within the time. It was now nearly ready, and would, it was hoped, be published soon. Hewson's works were also in the press. The attention of the council had also been directed to the valuable character of certain papers and communications published in the transactions of the medical societies, and some of these, which had appeared prior to the commencement of the present century, had been considered worthy of republication. A volume of obstetrical essays had been selected by the sub-committee, aided by Dr. Simpson, of Edinburgh, who had undertaken the office of editor. The papers and prize essays of the French Academy of Surgery had also been examined, and a series of essays on the head and neck would be published by the Society in one volume. The works of Hippocrates, a series of medical essays, several publications on medical ethics, and general indexes to the medical journals, were also proposed.

The report then proceeded to acknowledge that many valuable hints had been received from members in different parts of the country, and very great assistance from the honorary local secretaries, of whom about thirty had been appointed during the past year, in addition to the gentlemen already holding that office. It concluded by stating that it was the object of the council that the members of the Society should derive all the benefit that possibly could be obtained, and claimed that their intentions in that respect should be judged by the character of the works they had published.

The treasurer's report was then read, from which it appeared that the petty cash, advertisements, and expenses, amounted to £27 17s 11d; the ... orial, to £131 5s; the book-binding, to 108 11s 9d, paper, to £306 12s 8d; the printing, upwards of £500; a donation to the secretary of £157, and his salary for three-quarters of a year, £118 2s 6d. At the end of the last year there was a balance of upwards of £900; the subscriptions of 2105 members amounted to £2214 13s; interest from the Union Bank, £23 11s 8d; and dividends, £5 13s 10d. In addition to this there were certain sums resulting from the subscription of members desirous of obtaining the books published during the first year. At Ladyday last, when the treasurer's accounts were audited, there was a balance of £2076 16s 5d, since which date there had been received £53 16s, making a total of £2130 12s 5d, and moneys paid away, leaving a balance of £571 14s 10d.

The report of the council was then adopted, after which the ballot for the officers and council took place, and the following gentlemen were elected:—President: J. A. Paris, M.D., F.R.S., President of the Royal College of Physicians. Vice-Presidents: W. P. Alison, M.D., F.R.S.E., Professor of Medicine in the University of Edinburgh; Sir Benjamin C. Brodie, Bart., F.R.S., Sergeant-surgeon to the Queen; Sir William Burnett, M.D., F.R.S., K.C.H., Inspector-general of Fleets and Hospitals; W. F. Chambers, M.D., F.R.S., K.C.H., Physician to the Queen and to the Queen Dowager; Sir James Clark, Bart., M.D., F.R.S., Physician to the Queen and to the Prince Albert; Sir Philip Crampton, Bart., F.R.S., Surgeon-general to the Forces in Ireland; Sir Alexander Crichton, M.D.; W. G. Crosse, Esq., Norwich; Joshua Henry Davidson, M.D., First Physician to the Queen for Scotland; John Davy, M.D., F.R.S.; Charles Hastings, M.D., Worcester; John Kidd, M.D., F.R.S., Regius Professor of Medicine in the University of Oxford; P. M. Latham, M.D.; Robert Liston, Esq.; Sir Henry Marsh, Bart. M.D.; Sir James M'Grigor, Bart. M.D., F.R.S.L. and Ed., Director-general of the Medical Department of the Army. Council: Henry Ancell, Esq.; W. R. Basham, M.D.; W. D. Chowne, M.D.; John Clendinning, M.D., F.R.S.; Bransby Cooper, Esq.; James Copland, M.D., F.R.S.; John Erichsen, Esq.; John Forbes, M.D., F.R.S.; Arthur Farre, M.D., F.R.S.; Cæsar Hawkins, Esq.; Edward Headland, Esq.; John Hilton, Esq., F.R.S.; Thomas Hodgkin, M.D.; Samuel Lane, Esq.; James Luke, Esq., Jonathan Pereira, M.D., F.R.S.; Benjamin Phillips, Esq., F.R.S.; G. O. Rees, M.D.; William Sharpey, M.D., F.R.S.; Samuel Solly, Esq., F.R.S.; George James Squibb, Esq.; Theoph. Thompson, M.D., F.R.S.; Erasmus Wilson, Esq., F.R.S.; Jas. A. Wilson, M.D.

The usual votes of thanks to the president, council, treasurer, secretary, and honorary local secretaries, were then proposed, and carried, after which the Society adjourned.

The meeting was very thinly attended.

SURGICAL SOCIETY OF DUBLIN.

[From our own Correspondent]

Meeting of the 18th of April.

R. Carmichael, Esq., President of the College in the Chair.

Dr. Bellingham produced for the inspection of the Society the heart of a female, in which a quantity of lymph was deposited on all the valves, viz., the mitral, tricuspid, and aortic, yet there had been, he said, scarcely a single symptom of endocarditis, and not one of the auscultatory signs of disease during the patient's life. She stated, on her admission to St. Vincent's Hospital, about three or four weeks ago, that her only complaint had been dyspnœa and debility, which commenced about three months before, and persisted until a short time previous to her admission. The limbs were now œdematous nearly as far up as the knees, and there was slight abdominal effusion; there were, however, no indications of disease in any part of the system, and upon accurate examination of the heart, no palpitation or unusual action of the organ was present. Dyspnœa existed to some extent in the recumbent position, but in the semi-erect posture there was little or none. The heart pulsated in the normal situation, there being no bruit or other abnormal sound whatever, and no dulness. The cardiac sounds were perfectly distinct and regular. This was the condition of the patient until within a day or two of her death, which occurred in ten days after her admission.

The autopsy disclosed the very extensive evidences of disease seen in the preparation, namely, a large mass of lymph, which almost entirely closed up the mitral orifice; the lymphatic depositions on the semilunar valves of the aorta, and on the tricuspid, had more resemblance to vegetations. One of the kidneys was in the condition characteristic of the first stage of Bright's disease, but the urine during life presented no traces of albumen. The liver had the nutmeg appearance indicative of congestion. There was, as before observed, anasarca of the extremities, and slight effusion into the abdomen.

The case, Dr. Bellingham observed, was a very remarkable one, showing the existence of very extensive endocarditis in a perfectly latent condition, the only symptom of cardiac disease, as he had before remarked, having been a certain trifling amount of dyspnœa. Upon coming to the hospital she had not one symptom of the disease: there was no pyrexia, scarcely any dyspnœa in the semi-erect posture, and she was even able to sleep in the recumbent position. The only secondary symptoms were anasarca and slight ascites. All the circumstances of the case, Dr. Bellingham observed, appeared to mark it as one of anæmia; the impulse of the heart was that species of sudden tap peculiar to the anæmic condition, and the patient sank under gradually increasing debility. The pulse, however, remained perfectly regular to the last, and amounted to 120. The woman had been subjected to a reverse of circumstances. She never had rheumatism.

Dr. Benson read the details of a case of diabetes, together with some remarks upon the disease. He was induced to do so, he said, from having had under his care lately at the City of Dublin Hospital three patients affected with this disease, on one of whom he had an opportunity of making a careful post-mortem examination, and he brought the subject under the notice of the Society in the hope that on discussion some useful hints might be elicited respecting the nature and treatment of this curious and formidable disease.

Thos. Kearney, a pedlar, aged forty-eight, admitted to the hospital on the 12th January, 1846, was a married man, of sandy complexion, and of the nervous temperament, below the middle height, very thin and appearing to be at least ten years older than he really was. He had been much exposed to the vicissitudes of the weather in the fickle climates of England and Ireland, and had many reverses of fortune, but never was of intemperate habits. About fourteen months before admission his thirst became excessive, and his nights disturbed by the necessity of frequently rising to pass water. His flesh wasted, and his strength failed, though he ate much more than formerly, and with a craving appetite, which, if not speedily and generously supplied, was followed by a most distressing sense of sinking and prostration. He also had occasional attacks of water-brash.

On the 5th of last May, about six months after the complaint first attracted his notice, he was admitted into the Northern Hospital, Liverpool, where he remained some weeks, and left much relieved, the urine being reduced to five quarts a-day, about half the quantity he passed on admission. His diet while there consisted of meat, griddle bread made of wheaten meal, a quart of ale daily, and some tea. The medicine he got seemed to have been the carbonate of ammonia. In the autumn and early part of the winter he was in one or two of the Dublin hospitals, and came under Dr. Benson's care, as above stated, on the 12th January. His symptoms then were vertigo and headache, pains in the cheeks, impaired sight, defective memory, irritable temper, great debility, unsteady gait, excessive thirst, sweet clammy mouth, voracious appetite, burning sensation in the epigastrium, pains and weariness in the loins. His tongue was reddish at the edges and tip; his gums swollen and tender; teeth a little loose; abdomen rather tympanitic; bowels too free, though more frequently confined, and the discharges pale and unhealthy. His pulse was 80, and feeble; sleep disturbed with dreams; feet cold, but not swollen; skin harsh and dry; urine pale, very abundant, and of the sp. gr. 10·37, smelling faintly,

like fresh hay, and having a taste, as he described it, like turnip-water.

Next day a portion of his water, of which he had passed fourteen quarts in twenty-four hours, afforded on evaporation a very abundant syrup. He was ordered a pound of beef and a pound of mutton, coffee, without sugar, and a small quantity of toasted bread, daily. A pill containing opii gr. ij, acet. plumbi gr. ij, ter in die. In a couple of days he begged to be allowed three pounds of meat instead of two

On the 20th, when a week under treatment, the urine was of the same specific gravity, but reduced to twelve quarts in the twenty-four hours; thirst less; bowels too free; said he was rather better in every respect, except his head, which ached even more than before.

On the 27th, a fortnight under treatment, he felt better in every respect; urine diminished to seven quarts, bowels regular. Ordered to walk out as much as possible when the weather permitted, with warm clothes, continuing the same medicine and diet.

March 1. Continued to improve during the previous month; had occasional headache, and frequent heartburn, for which latter he took, with great relief, sodæ ex sic. gr. xx ter in die. When he came into the hospital his mouth was so parched that he kept a plug of dry meat, or some such thing, constantly in it to solicit the secretion of saliva He could now, however, do without this. His walks and exercise were gradually lengthened. Weakness in his knees was most complained of; his bowels were regular; urine reduced to four quarts, and of the specific gravity 1030 About the middle of March he professed himself nearly well, but though much improved he (Dr. Benson) could not consider him cured. The urine was reduced to four quarts in twenty-four hours, but its specific gravity never fell below 1030, his appetite and thirst were very much diminished, still much above the healthy standard He was advised to leave the hospital, but preferred staying a little longer, fearing he could not yet obtain for himself the liberal diet allowed him there. After this he often complained of headache, heartburn, pain in the stomach, &c., but Dr. Benson took no notice of him, thinking he made the most of his ailments, for the purpose of securing himself in his present comfortable quarters.

On Thursday, the 2nd of April, at the morning visit, Dr. Benson was informed that the man had spent a very restless night, "going about the ward, and quite out of his mind." There was now an expression of fatuity in his countenance, the skin of which had a bluish tinge. His skin was cold; eyes natural; tongue clean; but he unceasingly pushed it out and drew it back, as if instinctively searching for drink. He drank freely whatever was given to him, but asked for nothing. He answered questions incoherently; but he was neither comatose, nor violent, nor was there paralysis of any limb. It could not be ascertained that he was in any pain, but he winced when the epigastrium was pressed. His feet were stone cold; pulse frequent and feeble, and he had passed water involuntarily in his bed—the quantity passed, as far as could be guessed, being much less than he was in the habit of evacuating. Counter-irritants of all kinds failed to arouse him. He became perfectly comatose next day, and on the day after (Saturday evening) expired.

The body was examined on Monday morning. It was greatly emaciated; the skin harsh and rough; not discoloured. The abdomen, when open, exhibited no sign of peritoneal disease. The liver was healthy; the omentum healthy; spleen somewhat enlarged; intestines sound. The stomach looked healthy externally, but felt enormously thick, and presented the hour-glass contraction in a very marked degree. On opening it, large rugæ stood out prominently from the surface, and occupied both large and small extremities, every part in fact except the lesser curvature. They were thick, firm, and running in all directions, and could not be obliterated. The mucous membrane was highly inflamed, presenting the punctiform, capilliform, and maculated vascularity. The kidneys were greatly congested, yet not softened or enlarged. The vessels were so thoroughly injected with blood, that the tubular and cortical portions seemed at first to be with difficulty distinguishable from each other; but they presented no other signs of disease, no deposit, no change of structure, nor any result of inflammation. Perhaps the capsule was more easily removed than from a sound kidney. The ureters and bladder were sound; the latter contained a few ounces of urine, which was kept for analysis. The lungs, though usually tuberculous in diabetic patients, were in this instance perfectly sound, excepting only a few inconsiderable pleuritic adhesions of long standing. The heart also was quite sound; but its coronary vessels were distended with air, and on opening the left auricle a large quantity of air bubbled up with the blood. The pericardium contained more than an ounce of serum. The bones of the cranium were thin, and easily broken, and readily separated from the dura mater, which lay loosely on the brain; and between the two latter, that is in the bag of the arachnoid, a good deal of serum—probably an ounce—was found; there was a little also in the sulci, between the arachnoid and pia mater, but the arachnoid was everywhere transparent. The surface of the brain was very vascular, and the red points in the medullary substance when cut into were large and numerous. The cerebrum was of the average degree of firmness; but the cerebellum was soft, though no where in any marked degree. The ventricles contained half an ounce of transparent and almost colourless serum. The choroid plexus was pale, and filled with the little serous cysts commonly called hydatids. The corpus striatum, thalami, fornix, septum lucidum, &c., were normal.

In his observations on the foregoing case, Dr. Benson said there could be no question, he supposed, but that the cerebral affection was the immediate cause of death. But what gave rise to that?—was it owing to the gastritis so decidedly marked, or to any metastasis of irritation from the kidneys when the man was convalescent, or to the deteriorated condition of the blood, from the long-continued drain exerted on its constituents in the kidneys? We know that in Bright's disease the occasionally fatal results by head symptoms depend either upon the loss to the blood of its albumen, or its being poisoned by an accumulation of urea. Could any similar effect result from the blood in diabetes? A curious fact, one too which gives probability to this conjecture, is, he observed, that the urine found in the bladder after death was only of the sp. gr. 1013, just the weight of urine in decided cases of Bright's disease. Death from cerebral disease was he observed, very rare in diabetes, but as the patient all along complained of headache, the brain was probably the weak organ, and the morbid action, as the original disease subsided, fell upon it in preference to the lungs, by which death generally carries off its victim in diabetes. None of the numerous opinions respecting the proximate cause of the disease appear, he observed, to be established in a satisfactory manner. Willis, who first detected sugar in diabetic urine, attributed the disease to a dyscrasy or intemperament of the blood, resulting from a morbid action of the assimilating powers. Home, Cullen, Rollo, and Prout all assign, as the cause, a defect in the assimilating organs. Rollo says, we allege that this disease consists of an increased morbid action of the stomach, with too great a secretion of, and an alteration in, the quantity of the gastric fluid, producing saccharine matter by a decomposition of the vegetable substances taken in with the food, and which remain unchanged. MM. Mialhe and Contour think there is no increased formation of sugar in the stomach, but a want of power in the blood (from deficiency of alkali), to assimilate the sugar afforded by food. Dezeimais thinks that is a consequence of the thirst caused by chronic gastritis; the kidneys get too much to do, and their activity increases at the expense of the other organs. On the other hand, Mason Good, Dupuytren, Thenard, and others, consider the kidneys in fault. Dr. Baillie supposed a deranged action of the structure of the kidneys to exist, by which the blood there is disposed to new combinations, and that the chyle was so imperfectly formed as to cause the blood to be more readily changed into a saccharine substance by the action of the kidneys. Dr. Lubbock supposes that the skin ceases to throw off its carbonic acid, and that this, uniting with the hydrogen in the system, forms the sugar. Sir Henry Marsh, in his able paper, published in the Dublin Hospital Reports, also attributes the disease to the interrupted action of the skin. From the dissection detailed, can we, Dr. Benson asks, form any opinion as to the proximate cause of diabetes? Perhaps we may come near it by stating what is not the cause. No one, he would say, would contend that the disease within the cranium was the cause. Its contents are generally found healthy, and their diseased condition in the present instance was clearly an effect, not a cause. Were the kidneys the cause? He hardly thought there was enough there to lead any one to such a conclusion. The diabetes lasted a year and a half, yet the kidneys showed no change in bulk, consistence, or colour. They were only more vascular than usual—an appearance which they might assume in a few hours. Is it to be believed that they could have been even in a state of excited action for eighteen months without some alteration in structure? Increased duty they had to perform; but this increase did not originate with them. It was not an excited action, else they would have suffered more. Nor do any dissections made by others show much disease of these organs. Was the skin in fault? Doubtless it was; but secondarily, Dr. Benson thought. It is not the earliest symptom in general, but it comes on in the progress of the disease, just as it does in dysentery and many other affections; but if it were the first symptom, why should thirst be so early and so prominent a symptom? Thus, by the method of exclusion, we arrive, he thinks, at the stomach as the real fons and origo mali.

At the conclusion of his paper, Dr. Benson further observed that both from reading and experience the stomach would appear to him to be the organ most constantly deranged in this affection; at least gastric symptoms are either the first or amongst the first symptoms attendant upon the disease. No doubt the skin and kidneys may very soon be drawn into diseased action, and the blood also; but the question to arrive at is, what is the first link in the chain? Where does the morbid action commence? In the treatment he considered the use of animal food of primary importance, conjoined with which he had given opium and acetate of lead with decided benefit, the latter being known to be a powerful astringent as well as sedative. He looked forward to very beneficial results from this treatment, and they were very satisfactory up to a certain time, at which the case took a change for the worse. The urine had diminished in quantity so much as from fourteen to four quarts in the twenty-four hours, and the man's strength was returning. He complained only of headache, which he had on coming to the hospital, and which on that account could not, he considered, be attributed to the treatment. A curious effect produced by the opium in this and many other cases in which he had given it, was (Dr. Benson remarked) its regulating and keeping open the bowels—a fact which was observed in the present case, notwithstanding the acetate of lead which was given along with the opium. This man's bowels, too—a circumstance unusual in diabetes—were very free on admission. This effect of opium was also verified in a very marked manner in a case of diabetes which had occurred during Dr. King's residence in the hospital, the history of which had been very accurately noted by that gentleman. Besides the animal diet and the use of opium, great attention should in all cases be paid to the state of the stomach, when, along with emaciation, there exists tenderness in the epigastric region, and the other signs of chronic gastritis or dyspepsia. Instead of general bleeding, as strongly recommended by some, Dr. B. would have much faith in the efficacy of topical bloodletting, and regretted not having resorted to the practice in the present case; but when the patient came under observation, these symptoms were not urgent. In cases of diabetes, then, of future occurrence, his treatment would consist, he should say, in the employment of opium, with or without the acetate of lead, leeching the epigastrium, warm baths, and animal food. He hoped the subject would elicit some remarks from the gentlemen present.

The President considered the details of Dr. Benson's case extremely interesting, and that in

the accompanying observations, though brief, there was hardly a point left unsupplied. Dr. Benson's views also, in reference to the stomach as the primary source of the disease, admitted, he thought, of very little question indeed. The healthy assimilation of the food, the president remarked, becomes interrupted by long-continued dyspepsia, and a deterioration of the great mass of the blood finally occurs. He had himself much faith in opium as a remedy in the disease (possessing, as it does, so great a power in checking the quantity of urine) until two or three years since. He gave it at this time in large doses, combined with lead, in the case of a gentleman affected with diabetes, and fatal head symptoms very quickly supervened, the patient having died in twenty-four hours. These results the president was inclined to attribute to the very sudden suppression of urine having given rise to effusion on the brain, for the urine was immediately reduced in quantity in a very remarkable degree—the exact proportion he at that moment forgotten. There was a disposition to head affection in Dr. Benson's case, but in that to which he alluded, there was no symptom of the kind until the opium was given.

Dr. Butcher remarked that pathology does little towards unravelling the mystery in which this disease is involved. In no two of many cases in which he had himself conducted the post mortem examinations did the same appearances present themselves, and this assertion was confirmed by the observations of Home, Dupuytren, Segalas, and a host of other learned investigators, whose several statements regarding the morbid condition of all the renal organs differed remarkably from each other; besides that, they as often found the kidneys natural. The same diversity of opinion holds with respect to the chylopoietic viscera. He therefore thought the assimilating functions primarily at fault, and that, in order to investigate this disease more closely, we must have recourse to the pathology of the fluids.

Dr. Geoghegan observed that the discovery of sugar in the blood would appear to throw some light upon the disease in question, in reference to its dependence on the fluids. Dr. Apjohn, whose high character for accuracy of investigation is well known, had succeeded in detecting sugar in the serum of the blood, as also had some foreign savant whose name he did not remember just then; and this fact tended, he thought, to support the view of the dependence of the disease rather upon the organs of assimilation than upon the kidneys.

Professor Hayran mentioned a case in which he had used dry cupping over the loins, with the most marked benefit. Dr. Hayran was disposed to look upon the sympathetic system as a very probable source of mischief in this disease, inasmuch as in a diseased condition of that system all the fluids are known to suffer deterioration. In the very imperfect knowledge, therefore, which still exists respecting the pathology of diabetes, he thought it would be very advisable to examine most accurately, both by public and private post-mortems, the condition of the sympathetic system.

The President had always endeavoured to excite the action of the skin by warm baths, at the same that he gave lead and opium, for he had never seen a case that was not accompanied by a dry scaly condition of the skin, &c.

Dr. Benson had observed cases attended with much perspiration, or even sweating, from time to time, do better. But the skin, he thought, did not always present that dry, harsh, rough character. In the advanced stages of phthisis, and other diseases, more particularly in dysentery, a dry hard state of the skin may be observed even when there has been previously copious perspiration. An improvement in the state of the digestive apparatus might be expected to effect a corresponding improvement in the functions of the skin. If, as appears clear, the kidneys are not the seat of disease, dry cupping, though useful, could not be expected to cure diabetes. The kidneys acquire increased vascularity from the great increase of action to which they are subjected, but this must be looked on as a consequence, not a primary cause of the disease. Want of action in the skin might cause increased secretion of urine; but to render the latter saccharine something else is required. The sugar must be supplied by the blood, and the blood must derive its supply from the digestive organs, where we know that sugar actually abounds in this affection. The alvine discharges have sometimes been coated with crystals of sugar - grated over. Was this by any deranged action of the kidneys?

Dr. H. Kennedy had opportunities of witnessing the occasional termination of diabetes in phthisis, the diabetes appearing to have sunk completely in the shade, and the urine becoming rapidly decreased in quantity, and losing its increase of specific gravity. He had also known a diabetic patient to be attacked with phlebitis of the lower extremities, of which he died.

The President mentioned a couple of cases, tending to show that arteritis might also be a consequence of the disease in question. One of these, a gentleman under his own care, got Pott's gangrene, of which he died. The other was under Mr. Adams' care, and also died of Pott's gangrene. He spoke now, it should be observed, of inflammation, not of ossification, of the vessels.

Some further unimportant discussion ensued.

PATHOLOGICAL SOCIETY OF DUBLIN.

Meeting of March 14th, 1846.

Mr. Adams in the Chair.

Dr. Green would only occupy the attention of the Society for a very short time, he said, while he mentioned a few particulars connected with a pathological specimen of patulent aortic orifice and dilated heart. The specimen, he observed, had in itself nothing that was new to the Society, similar ones having been so frequently before them on former occasions. A well-marked bruit had existed during life over the origin of the valves, and became louder in the course of the aorta, being heard also in the carotid and subclavian arteries: here, too, there was fremissement and a returning bruit. The pulse at the wrist was very perceptibly later than the impulse of the heart, a sign which he might here observe, is a particularly valuable one; while that laid down by Dr. Corrigan (visible pulsation), though often present, is frequently absent; but the one just mentioned is never wanting. What he was most anxious to direct the attention of the Society to, however, was the existence of a species of false impulse visible at the top of the sternum, and so deceptive at first sight as readily to give rise to a suspicion of the presence of aneurism. However, the diagnosis made was: effusion into the right cavity of the thorax, with a portion of solidified lung lying over the trajet of the aorta, pressing against the sternum to such a degree as to cause it to bulge forwards, and to produce almost complete dislocation of the clavicle at the right side. A material assistance in making this diagnosis, Dr. Green remarked, was derived from observing that the bruit audible over the prominent portion of the sternum was not at all commensurate in extent with the area of dulness, though it was louder at this part than over the heart itself. Dr. Green said he found he was not singular in the conclusion he had come to in making a diagnosis of this case, for a precisely similar one is recorded by Dr. Henderson in the *Edin. Med. and Surg. Transactions*, in which that gentleman had some difficulty in deciding whether aneurism did or did not exist. In the present case the aorta was slightly diseased, and dilated to a considerable extent, and there was dilatation without hypertrophy of the right ventricle. Impulse being a sign to which so much importance is attached in cases like the present, that Dr. G. thought it would be well to record every instance in which this sign proved fallacious, and for this reason principally he was induced to mention the present case to the Society.

Chronic Enlargement of Patellar Bursæ.

Dr. Adams presented casts and specimens to illustrate the pathology and surgical treatment of the chronic enlargement of bursæ over the patella. Dr. Adams would confine his observations exclusively to these chronic enlargements, which were unaccompanied by pain or other inconvenience than that which arose from their size, and the deformity they produced. The cure of this disease seems quite within the power of surgery; but which of the different modes recommended—each of which has been successful—is the best? This seemed to Dr. Adams to be a matter worthy of consideration. The methods by puncture, by subcutaneous incision, by injection, by extirpation, and by free incision, have all had their advocates. It would take up too much of the valuable time of the meeting to discuss the comparative merits of these several modes; but Dr. Adams would beg to lay before the meeting a few casts and observations relative to this subject. Dr. Adams then read a case reported by Mr. M'Dowel.

Eliza Butterton, aged twenty-two, was admitted to the Richmond Hospital on the 11th of March, 1845, with a chronic enlargement of the bursa over the right patella, from which she experienced so much inconvenience that she was anxious to be relieved by any means thought advisable. The tumour was about the size of a hen's egg; the skin covering it had a natural appearance, it had an evidently fluctuating feel, and small foreign bodies could be distinguished in the fluid.

On the second day after her admission, Dr. Adams opened the tumour by a free longitudinal incision, extending from above downward throughout the whole extent of the enlarged bursa. A fluid of an oily appearance escaped, carrying with it numerous small pyriform-shaped bodies, of a whitish colour; and a few of these which, on inspection of the interior of the cyst, were adherent by slender pedicles, were detached from the lining membrane and removed; an oiled dossil of lint was introduced into the bursa, and light compresses and bandage applied.

On the third day, suppuration was established, and a poultice applied; no inflammation or constitutional disturbance whatever was excited; granulations were thrown out from the bottom of the cyst, and the cavity gradually became obliterated.

On the 20th day the granulations were so raised as to require the application of the nit. argent. She was discharged on the 10th of April, the 25th day after the operation, and for the ten days previous had been walking about without feeling any inconvenience.

The next case Dr. Adams had to adduce was that of Mary Moore, aged twenty-eight, a housemaid. She had a chronic tumour, situate over the right patella, which was as large as an orange. She applied to Dr. Power, who gave it as his opinion, that, if she wished for a radical cure, she should go into the hospital, and submit to an operation, which would confine her for at least a month; but, as she was unwilling to do this, he tried a palliative plan of treatment, by puncturing the tumour and letting off a great deal of its fluid contents; this was not followed by any inflammation, but having proved of little advantage, he advised her again to go into the hospital under Mr. A.'s care, which she did on the 19th of Feb. Mr. Adams now made a free longitudinal incision from above downwards into the tumour, and gave exit to about three ounces of a brown oily fluid, in which were seen floating shreds of lymph, and small bodies like boiled rice. The cyst seemed about three or four lines in thickness, and its anterior surface was remarkably smooth and yellow, like the interior of the aorta. Towards the back part of the cyst where it covered the patella, were seen large round transverse bands of yellow tissue, one of which was an inch long, of a cylindrical shape, and fully as large as the largest goose-quill. Mr. A. here exhibited this portion of yellow tissue which he thought it advisable to remove from the cyst to which it adhered by its extremities, while the rest of its surface, like some of the curved columns in the heart, was free all round. Besides these transverse fibrous bands, there were also rounded cartilaginous bodies, as large as peas, attached to the interior of the cyst by pedicles; these with their pedicles were cut out, and now exhibited. The cyst in this case had anteriorly attained such an extent that when its contents were fully evacuated, it formed a loose bag in front of the patella, which, as it could scarcely be expected to contract so much as to prevent deformity, Dr. A. thought it right to dissect the skin from the elliptical portion of the cyst constituting its anterior portion, and to remove so much of the cyst. This having been done, and the foreign bodies removed,

the wound was dressed as in the former case, but the time it took to heal was longer, and the suppuration of course more extensive, but no constitutional disturbance whatever followed the operation.

She left the hospital on the 29th of March, perfectly well, and it was truly surprising how much the thick cyst softened down, and what little projection of the skin, beyond what is natural, remained. A cast, taken by Dr. Green the day she was discharged from the hospital, showed what little deformity was observable: a line of cicatrix, about two lines broad and two inches long, from above downwards, in front of the patella, alone remained; excisions of the bursa situated over the patella, when in a state of chronic enlargement, has been recommended on high authority as the best mode of proceeding. Dr. A. had known this to be very frequently done, and although he might admit that in some cases such an operation might be judicious, still he must express his belief that such cases should form the exception; and that, as a general rule, the operation by a free incision is much the more preferable mode.

He had observed the dissecting out of the bursa to be a very painful proceeding, and in very large tumours could well conceive that it might (if not conducted with caution) endanger the knee-joint. Suppose, for example, a case such as was represented by the cast now exhibited, with the enlarged bursa measuring in its circumference thirteen inches, projecting from the patella seven inches, and consequently completely covering the patella above, below, and laterally. Here Dr. Adams remarked, while a free incision from above downwards would be done in a few seconds with but little pain to the patient, and without any immediate danger of injuring any of the subjacent parts, while excision of such a tumour would be a most severe operation, and it is quite possible that the synovial membrane of the joint might be opened if the greatest care were not used. Whereas the free incision from above downwards is quickly and easily done by any one; infinitely less painful, and the experience of three cases lately under Mr. Adams' care showed that the deformity which might be supposed to remain after the operation of incision into the thickened cyst, is really nothing. Dr. Adams prefers the operation of free longitudinal incision to punctures, injection, or seton, because although these latter means may excite sufficient inflammation to produce a radical cure, yet they are by no means so certain, and Dr. Adams thinks any operation in which foreign bodies are left behind likely to fail in radically curing the disease, because when these foreign bodies are pressed upon while kneeling, new irritation and inflammation arise, and consequent recurrence of the disease. Another great advantage of the free incision is its not being followed by any constitutional disturbance. Puncture, subcutaneous incisions, setons, &c., may all be followed by inflammation and suppuration of the cyst of the diseased bursa, and be accompanied by a decomposition of the fluid contents of the sac, the pus in such cases becoming remarkably fetid, and much consequent disturbance of the constitution, which is not removed until the fetid pus and gaseous contents of the inflamed bursa are freely evacuated. All these evils, Mr. Adams believes, are prevented by the operation recommended by him, of free incision from above downwards. True it is that in cases where the cyst is thick and capacious, as in the case of Moore, lately under his care in the Richmond Hospital, something more than mere longitudinal incision may be found necessary; the emptied cyst may, as in that case, form a loose bag in front of the patella; but in such cases the surgeon has only to remove an elliptical portion of the cyst, having previously dissected the skin from the cyst anteriorly. Such an opening, too, will enable us to see the bottom of the cyst, and remove with facility any foreign bodies or bands which may traverse this tumour, and which, if left behind, are calculated to cause a recurrence of the disease. In many cases, no doubt, the cysts are found much thicker than in any of the cases Mr. A. has met with; but he is strongly inclined to believe that in all cases the cyst will be absorbed if the plan of free incision and subsequent mode of dressing here recommended be adopted.

ETHNOLOGICAL SOCIETY.

April 29, 1846.

Sir Charles Malcolm, President, in the Chair.

Mr. W. S. Featherstone, Esq., Henry Hallam, Esq., and Frederick Bower, Esq., were elected fellows.

The paper read was entitled—"Observations on the Indian Tribes inhabiting the North West Coast of America, by John Scouler, M.D." Under this title Dr. Scouler has given a classification of the various tribes found between Behring's Straits and the Columbia River, and included between the Rocky Mountains and the Pacific Ocean. They are sixteen in number, which is very considerable for the narrow district within which they are confined. To the east of the mountain range, the Algonquin race alone occupies a territory exceeding that of the sixteen families mentioned. Even if we exclude the Esquimaux, we find there is a considerable variety in the physical features of the Indians of the north west coast of America, as well as in their intellectual and moral character. Comparing them *en masse* with their neighbours east of the Rocky Mountains, they have a more extensive range of ideas, are less inflexible in character, and more imitative, and, instead of the hard-heartedness of the Iriquois, the ferocity of the Carib, or the impassable cruelty of the Brazilian, are truly humane: the custom of scalping is unknown; prisoners taken in war are rarely put to death after the excitement of the contest has subsided, and they are never exposed to lingering tortures. The elaborate carvings of one of the sixteen families—the Haidah—is, in Dr. Scouler's opinion, equal in skill to any thing displayed by the Mexicans, and shows how small an amount of civilisation might suffice for the construction of the monuments of Chiapa or Yucatan. The Flat Heads, Cayuse, and Shahaptans are remarkable for their moral character and religious culture. Long before the arrival of Christian teachers among them, they had learned to observe Sunday by spending a part of it in prayer and religious ceremonies, and by setting aside their usual labours. The paper was full of learning, and called forth observations from Dr. Latham and Dr. King, who have devoted themselves of late to the history of man in that part of the world, and whose valuable researches have already been the subject of comment in the *Medical Times.*

REVIEWS.

Spinal Affections, and the Prone System of treating them. By James Coles M.R.C.S. &c. Post 8vo. pp. 320. London: Houlston and Stoneman, 1845.

This work consists of a practical exposition of the advantages of treating various spinal affections, both acute and chronic, by the prone position, as first suggested by Dr. Verral in 1823. In the hands of that able practitioner, the system succeeded admirably, and not unfrequently in cases which had previously resisted other methods of treatment. Since his time, the plan has been more extensively carried out, and especially so by the author of the volume before us, who has contributed many improvements to the original mode of practice. The book embraces a simple, but intelligible, anatomical and physiological comment upon the spinal column and its contiguous structures; a description of the varieties and causes of spinal distortion, with a consideration of the influence it produces upon the general health of the sufferer; a summary of the different means used aforetime, and at present, for the relief and cure of these painful affections; a minute description of the mode of employing the prone system, and a selection of cases illustrative of its beneficial effects. The work contains a great deal of useful information of a practical nature, and occasionally displays a very creditable amount of research. It is especially calculated to be of use to the general reader, but the medical practitioner will find much in it that he may consult with advantage.

We cannot, however, close the book, without noticing two extraordinary errors contained in it—and they are the more extraordinary because of the contrast they furnish to the better material they mingle with. In a foot note at p. 224 we are informed that "the father of spine stretchers was Dr. Procrustes, an eminent physician in the ancient times of Greece, and we are told that when that great man met with a patient more crooked, or shorter than he, the doctor, thought he should be, he laid him upon his own bed which he had invented, and stretched him until he became of the exact length which he had determined that he should be."

What Mr. Coles can have been doing to let his brains run riot in telling such "a tale of a tub" as this, we cannot imagine. At any rate we must give him credit for being more familiar with surgery than with classics. Lest he should ever repeat this strange story, we beg to inform him that his distinguished physician—*torvus Procrustes*, as Ovid happily calls him—was no doctor at all, but a highwayman who scared all travellers away from his particular territory: hence his name, Procrustes, ἀπὸ τοῦ προκούειν. This said distinguished individual, besides deserving the honour awarded to him by Mr. Coles, of having invented the stretching system for curing deformity, and promoting growth, also invented the summary plan of shortening limbs that were too long, by simply lopping off as much as was exuberant. So that though he was not a practitioner, properly so-called, in surgery, he was an excellent operator, and immortalised both himself and his bed by the extent with which he treated his "patients."

At p. 243, "Hippocrates," says our author, "relates that the Scythian women seared the right breast, that the arm on that side might grow in strength." On consulting the old Coan, we find him saying that at certain seasons of the year, the humidity was so great in Scythia that the juices of men would not dry up fast enough, and they became soft and smooth-skinned, and resembled women—sed propter pinguedinem, et carnis glabritiem, forma inter se sunt similes. To avoid this *likeness*, the *men* used to have their breasts burnt, that the humidity might be dissipated. The only *women* who had their breasts burnt off were the Amazons—they parted with the right organ, that it might not interfere with the motions of the arm in using the bow or the javelin.

A Manual of Natural Philosophy: with Recapitulatory Questions on each Chapter, and a Dictionary of Philosophical Terms. By J. L. Comstock, M.D. and R. D. Hoblyn, A.M. Foolscap 8vo. 1846. London: Adam Scott.

This work is, for the most part, a reprint from the American one published by Dr. Comstock. It has the advantage of the able editorship of Mr. Hoblyn, who, besides having elucidated several parts, in the otherwise excellent original, has also supplied much new matter on the subject of heat and the steam engine. As the manual now stands, it presents almost everything, both diagrammatic and descriptive, that the student can want in an elementary investigation of the physical sciences, both in their common and their complex forms. The illustrations are particularly easy and intelligible, and the text perspicuous and simple, and yet, not wanting in profundity, when elaborate details are called for. We have derived much pleasure and profit from a perusal of the volume, and we gladly introduce it to all whom it may concern, as a most excellent digest and summary of the more important, as well as of the popular, truths of natural philosophy.

Diluvii Testis.—Dr. Albert Koch, it is stated, has discovered a colossal skeleton of the fossil reptile, called the basilosaurus by M. Harlan. It is one hundred and four feet long; the solid portions of the vertebræ are from sixteen to eighteen inches long, and from eight to twelve inches in diameter. This monstrous reptile was carnivorous; the eyes were large, and projected in front of the head; the limbs were in the form of oars, and were small in proportion to the size of the animal, although doubtlessly sufficient to direct the body of this enormous animal through the waters, of the rivers and seas, which he frequented. Every thing proves that these animals were very numerous in the seas, bays, and estuaries, which formerly occupied the entire country now covered by the tertiary formations of Alabama.

TO CORRESPONDENTS.

M. D. *is certainly liable. We doubt, however, the intention of the Apothecaries' Company to prosecute in such cases.*

M. R. C. S. London, *mistakes entirely the value of a purchased German diploma. It neither carries weight nor increases the respectability of its possessor.*

L. W. R. *guesses rightly.*

S.—*The next examination at the Royal College of Physicians, London, will take place when a sufficient number of candidates have entered their names for that purpose. S. will find any further information he may require in our last students' number.*

We fear Amicus *does not sufficiently understand the puzzling question of medical reform. To frame a bill which will please all parties passes the skill of our best legislators.*

J. G.—*We really regret we cannot oblige our correspondent by giving an average. Such things vary much, and we are not aware of any statistics to refer to.*

An Old House Surgeon, and A Well Wisher to University College Hospital, *are thanked for their information. Our correspondents will see that we have fully treated the matter in another place.*

K. (Bath) *is recommended to inquire of the Post-office authorities. The fault does not lie at our office. K. mistakes in saying that his library only receives* one *volume of the* Medical Times *annually for his guinea. We furnish* two *for that sum—the two, at least,* equalling *in the amount, as well as value, of their scientific information more than twenty booksellers' volumes of half a guinea each.*

Amans *will oblige us by giving his name and address confidentially.*

Tyro.—*Our* Pharmaceutical Number *for May, now ready, contains a complete comparative table of the French and English weights and measures.*

A Navy Surgeon.—*Mr. Guthrie's lectures are delivered every Saturday, at 2 o'clock, at the Westminster Eye Hospital. A large number of gentlemen usually attend. We advise our correspondent to be early if he desires a good place.*

Dr. Rigby's *lectures will be resumed in our next.*

A Student.—*Dr. Clay's residence is Piccadilly, Manchester. Some of the numbers asked for are out of print, but we have reason to think that our valued correspondent—a practitioner of whom not only Manchester, but the provinces, may be proud—purposes to publish his numerous cases of ovarian extirpation (originally published in this Journal) in a separate form. The first case of ovariotomy performed in England was performed not by Mr. Walne, but Dr. Clay, and was remarkably successful.*

A Surgeon *need anticipate no change this session.*

W. S.—*The Journal named has notoriously fallen 50 per cent. in its circulation. Our correspondent may satisfy himself on this head by a reference to Messrs. Simpkin and Marshall, or Messrs. Longman and Co.*

A Poor Man *should consult a medical practitioner or become an out patient of one of the hospitals.*

Medicus *cannot do better than possess himself of Dr. Guy's volume on Medical Jurisprudence. The most elegant compendium on the subject in any language, and beyond question the best in our own. For the other work we think our correspondent should select that by Quain and Sharpey.*

THE MEDICAL TIMES is the only Medical Journal published at its own Office, and which is free from the control of all Booksellers and Publishers. Gentlemen may procure it by an order on any Newsman or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfrae, or an order on some party in town. One Guinea IN ADVANCE, which will free them for twelve months. Half-Yearly Subscription, 13s; Quarterly, 6s. 6d. No number of the Medical Times can be forwarded, except to gentlemen paying in advance.

THE MEDICAL TIMES.

SATURDAY, MAY 9, 1846.

"'Tis the first virtue, vices to abhor,
And the first wisdom, to be fool no more."
IMITATIONS OF HORACE.

It would be little less than a miracle to witness any individual, or association of individuals, working out great social advantages, and winning the good opinion of all just men, without incurring the animosity and antagonism of envious and froward rivals. The brighter the glory of the sun, the darker are his shadows. Envy is the invariable attendant on merit; and the more deserving the object, the greater is the cause for detraction. The man that could silence Envy, would be a god—ay, more; for Envy has her exemplar in the records of heaven itself—in the defection and malignancy of the first rebel. It is, indeed, a truism which all experience confirms, that merit may often be measured by the amount of calumny that it evokes; as it is the pulse of reaction that often gives us the clearest estimate of the state of the patient.

Judging by this rule, the Committee of the National Association, and more especially the honorary secretaries, have, up to this time, acquitted themselves most honourably of the laborious duties which have devolved upon them in their responsible situation as advisers of their professional brethren. Never have men been more abused, or suffered more misrepresentation; but we trust that the promise of a more "substantial reward," dropped by the able Chairman of the Committee, at the recent public meeting, will be realised, and some compensation thus given, as a set-off to the long account of slander in which the Profession stand indebted to these gentlemen.

We have regretted, most deeply regretted, the dissonance of sentiment, and the vexatious disunion of policy, which have, during the whole of the agitation of the medical question, troubled, if they have not impeded, the labours of the enlightened leaders of this important Association. When we have believed that this opponency was honestly maintained by men of character, station, and ability, we have refrained from employing severity of language, or even from assuming a tone of reproof. Each individual is entitled to an opinion, and to a hearing; and we are ever anxious to encourage a fair and candid discussion of *every subject* whereon disagreements may exist. This has been, and ever shall be, the character of this Journal.

With a tenderness leading almost to error, we have given but little attention to the misdoings of the Associated Surgeons, except to treat them with that light ridicule which, to a sensitive mind, has all the bitterness and usefulness of rebuke, but to a callous heart is ineffectual for any good purpose. The errors that we have, from time to time, exposed, would have brought a blush of shame to the cheek of most men not utterly insensible to public opinion; but it appears that these half-dozen gentlemen, or some of them, either could not feel shame, or would be more ashamed to show it. Our last article, however, seems to have awakened in them a sense of public decency. Their usual weekly meeting was not held on Monday night, and probably both the Profession and public morals will be spared the discredit of their recurrence. We congratulate these persons on the prudent course they have so far taken, and, in the expectation of a full measure of repentance, we are as much inclined to give them a condonation for all their past offences as we may presume they are anxious to crave it. To show them that we are disinclined to inflict unnecessary punishment, and that forgetfulness of error is more congenial to us than reproach, we forbear, on this occasion, to give their numerous evil practices that exposure of which we last week gave them a pledge. We can scarcely doubt, however, that they are very willing that the pledge should be revoked, and that the debt stand over for future settlement. If we are in error, we have still the alternative to let the details accumulate, and pay all off in the lump.

We must, however, warn them, that if they persevere in assuming functions to which they have no legitimate claim, in deluding public opinion, in sowing discord broadcast over the Profession, our duty to truth and honour will require from us a rigid exercise of those judicial powers with which we are invested. Let us have no more announcements of "phantom breakfasts," for the entertainment of invisible guests, no more agitation of conventions from local Associations that never had an existence except on foolscap, and for whose delegates a set of bells would be a most appropriate ornament. These pretensions, this deceitfulness, this organised imposture of self-styled Committee-men, who have not an Association *with one single member* to support them, is sickening in the extreme to all who would not have the exposition of public opinion covered with ridicule and discredit. It is, indeed, intolerable. If the object of these people be notoriety, we assure them that they shall have a sufficiency, though, perhaps, the *distinction* will not be of the character they seek. They must remember that men can only reap what they have sown. With them, perhaps, it is a matter of taste, no more, whether martyrdom be in the cause of political unprincipledness or political virtue. *De gustibus non disputandum est. We* have a peculiar weakness in favour of honesty of purpose—a quality which experience would seem to show totally disqualifies us for some of the busy scenes of public life. At all events, it gives us no love of their's.

At the present juncture we have no patience for dissension, especially promoted through imposture. It is *no longer* a question whether the General Practitioners shall seek for the establishment of a new college, or for emancipation in the College of Surgeons. The time for such a doubt is gone by. The numerous demonstrations which the Council have made of their determination, and of which the recent oration, and the conduct of the Council thereupon, were among the most flagrant examples, have succeeded in chilling every hope even of the most ardent reformer who has the least practical acquaintance with the matter. No justice in that quarter *can* be obtained. The Council have torn away the mask, and the film has dropped from the eyes of the members. The truth, in all its glaring hideousness, is made visible. It is idle now for any set of individuals, were they as respectable and influential as those who head the National Association, to bridge over the chasm. The field of contest indeed is virtually abandoned; a random shot from some undisciplined malcontent may now and then be heard, as his party makes

its retreat, but regular warfare is at an end, and the Council of the College unquestionably stand victors over the scene. If they remain so, it will be the fault of the Profession. We must change our tactics; for it is the height of obstinacy and infatuation to continue a system of defence or reprisals which has on every occasion terminated in our defeat.

The National Association has suggested the only plan that can possibly be attended with immediate benefit; it is founded in the actual wants of the Profession, and will satisfy them; it is just in its principle, and will command respect; it is practicable in its policy, and will be crowned with success. As the great Lord Bacon has well said, "Let a man in the choice of his mean, rather choose the *fittest mean* than the greatest mean; and rather thos that deal in certain things, than those that are general." Generalities are, in fact, the toys of reason rather than the tools; they serve for show, for discipline, and for eloquent appeals; but they are commonly useless in business, and impede all rational progress and profit. Some men are constantly endeavouring to leap before they can crawl; their efforts are exceedingly ridiculous to the more judicious and experienced; but there will always be found men fools, and vain enough to become imitators.

Dicere quid si forte Jocosius, hoc mihi juris cum venia

A CERTAIN old man, who had lived an uncertain number of years ago, consoled himself, in the midst of his troubles, with the reflection that he was not single in them, and that he had probably no greater share than fell to the lot of his neighbours. This fellow was a philosopher, no doubt of it, and a practical one, too, or he would never have laughed at tribulation merely because he had plenty of companions in it. His propensity was a very happy one, to say the least of it; and was probably peculiar to him, which is saying the most of it; for we have never heard of an imitator of the maxim who has fared as well as its father. The good old philosopher, however, was decidedly in error, which might have been the fault of his organ of Comparison, or the fruit of a constitutional indifference to pleasure and pain. For had he fairly measured the joys and sorrows that were meted to him, in spite of himself, and contrasted these with the like visitations of his fellow-mortals, he would not have found the uniformity he fancied, but have discovered that fortune, like females, has her favourites, and that she smiles and frowns according to sundry hysterical freaks of her own, and not according to any set rules which might limit her vagaries. In fact, he would have discovered, as we have often done, that, whatever be a man's troubles, there are some that have less and others that have more than he, and, therefore, that there is no such thing as equality in the distribution of pleasure and pain to the human recipients thereof.

What holds true in particular, holds equally true in general, and we, consequently, find that there are certain avocations in life that are more or less free from annoyance than others. Here, now, is a case in point. Just as we were in the midst of this significant train of thought, we were summoned from the desk, at the command of a gentleman, who, having duly delivered his card, and declared his business to be important, was ushered into the consulting room. A gentleman, with his card, calling upon a physician, naturally suggested the idea of a patient with a guinea, perhaps with a couple—of course it was—what else could it be?—and we willingly threw down the editorial pen to take up its feathery companion, sacred only to prescription-writing. There was ink upon our fingers, and we carefully washed it off; our hair was ruffled, as an editor's ought to be when he is busy in thought, and we brushed it into orthodox regularity; boots were exchanged for slippers, and a "fan-tail" for a dressing-gown —and all to look as a physician ought to look in the eyes of a patient who sends his name in his card! When we encountered the welcome visitor, sure enough he had the air and ease of a gentleman, though considerably less of an invalid visage than we had hoped for. He rose and bowed at our *entrée*, reseated himself, blew his nose, coughed, crossed his legs, and made himself as much at home as any man could do who meant to pay a fashionable price for his freedoms. Of course, he was a patient, and liked a little preliminary before detailing his case; or he might be a little nervous, and affected this *nonchalance* the better to recover a certain portion of breath of which he had become a loser by our sudden presence; or he might be a very shrewd fellow, curious in conning human nature, and to read well our title-page before entering upon his complaint. These, and other such things, we thought in less time than we have taken to tell them; and, after duly marshalling to our aid pen, ink, paper, and stethoscope, fell back into the arm-chair in calm consequence, and waited for the attack. The onslaught was made, not by a patient, but by a petitioner—not upon one's knowledge and professional skill, but upon one's pocket—not upon the physician, but upon the man, in whose heart it was hoped would be found a sympathising and patronising regard towards a poor Pole—a nobleman, of course, in his own country, but here penniless and out of place. It is not necessary that we should go into further detail of what we did and what we said, when the fellow's impudence had fairly evolved itself, and dissipated the golden delusion we had cherished for half an hour—the reader will guess all about it when we tell him it is very unlikely we shall have any such visit from any such source again.

Now, would this *itinerant* have ventured a similar attack upon the charity of a tinker, tailor, blacksmith, or other creditable artizan? We opine not, for his discretion would have taught him that in such quarters his aristocratic mendicancy would have met with little toleration. Would he have made the experiment at the house of a nobleman, a member of Parliament, or a private gentleman of consequence? No; because the liveried lacqueys in waiting would have warned him that their master's time was not to be trifled with. Would he have gone into a lawyer's office with such cool effrontery? No; for the very audience might have cost him something. But a doctor was fair game, and there was no harm in hunting him. Whilst sufficiently respectable to be competent to give charity, he was not too much so to be beyond the reach of any adventurer who might ask it. His time was valuable enough to keep him at home in expectation of professional engagements, and yet not too valuable to be engrossed by an idle caller who did not care what quantity of it he occupied.

As all men have certain troubles, so all situations in life have certain inconveniences; and as some men have more troubles than others, so are some occupations unduly visited with nuisances. Physic is one of these, as the case above recorded can testify, and as every medical man's experience can corroborate.

In the eyes of mankind at large a doctor is a strange compound of consequence and insignificance—of importance and indifference—sought after with eagerness, and shunned without hesitation. He is made everything or nothing of—caressed like an angel, or cursed like an ogre, according as he may be conferring a service, or asking compensation for one. To solicit his aid is one thing; to reward it, is another—few care about the trouble they give him, and fewer still care to pay him for it. He is recognised as everybody's property—pillageable at option, like a piece of waste ground—with no tribunal to inflict a penalty for trespass. He possesses (thanks to himself) a title to charitableness, which the public are only too happy to avail themselves of:—his opinion is no expense to him, they think, and therefore they are unmindful how coolly they ask for, and how carelessly they regard it.

The facilities which the medical practitioner affords for gratuitously soliciting his advice, have furnished also the inducement for an unceremonious demand of his presence, that his pocket may be preyed upon the more easily. Ladies, wanting to see you very particularly, and as quickly as possible, obtain an ingress into your audience chamber, and directly that you give them the meeting, most likely at some inconvenience, present you with a memorandum book of subscribers to some charity you never heard of, at the same time politely asking the favour of your name, and perhaps of rather more ready money than at that moment you may be carrying about with you. If you commit all your available material into their custody, you are indifferently thanked for it, and considered as having done nothing more than, as a gentleman, became you. If you decline the charity, whether from inability or inclination to further it—no matter which—you are forthwith scouted as everything that is bad, and your good name does the penance of your presumption ever after.

Parsons, and laymen too, possess extraordinary facilities for attacking the benevolent side of the medical practitioner; but they take precious care to reverse the attention to him as seldom as possible. A clergyman whom we once knew—may we never know his like again!—living in a conspicuous midland town, in consequence of various *faux pas* in debt, dissipation, and debauchery, was obliged to give his church and canonicals the slip, and betake himself into obscurity, until the storm that had gathered around him had somewhat lessened in violence. A certain set of deluded followers, who believed him to be a saint, because, like Cantwell, he had cunning enough to conceal his inner man, set about pulling him out of every difficulty—debt amongst the number. They importuned his medical man to forgive him a bill of many years' standing, and then coolly asked him for a further gift in *bonâ fide* money. To both of these calls he responded, and the reward he got was, that neither the principal nor his prototypes ever employed him again, and the first favour he subsequently asked at their hands, they refused him! What would they have said of him had he excused himself from walking a couple of miles, when requested to do so for nothing, to see a patient troubled with toothache? How he would have been stigmatised as unfeeling, for not gladly running the shoes off his feet in a gratuitous attendance upon a pauper, whom the parson would object to bury without his customary fees!

A common nuisance amongst us, now-a-days,

is for a fellow, dressed decently, to send his name up to you, saying he wants to see you particularly; and when you give him the greeting, he has got some choice lead pencils, some superior clarified quills, some superfine writing-paper, or a book of particular cheapness to sell! And a precious *sell* it is to the poor practitioner who commits himself to the interview, in the hope of profiting by it. Upon no class of men is this impudent deceit practised so unsparingly as upon medical men. And why?—because they are believed to be so foolishly generous as to tolerate the impertinence, and even to pay it for visiting them.

The only sure way for our fraternity to guard themselves from an illiberal invasion of their time, their talents, or their treasury, is to estimate their work and condition by the scale proper to them, and maintain inviolate the honour which is their due. Once permitted to be invaded, that honour is at a discount, and it recovers not easily its intrinsic consequence.

The young practitioner is especially liable to be the dupe of the many artifices practised upon the profession. Let him start in life with the grand leading rule, that, if he fail to "put money in his purse," nobody will pity him when the hour of poverty comes. Those whom he has been ready to benefit in his days of prosperity will be the readiest to blame him when adversity makes him its victim. Let him never give, gratuitously, his advice to people who can afford to pay him for it. If he do, they will value his prescription at a straw, and then desert him for others who will rate their opinions at a more estimable price. Let him not make himself too cheap, but consider his presence, summoned, as a fee in perspective, and ask for it, even in the face of the intruder, having pompously come to seek alms himself.

THE GOWER-STREET SCHOOL.

THE educational establishment in Gower-street, at one time known as Stinkomalee University, at another as University College and Hospital, have never been highly estimated by public opinion. Justly or unjustly, the world never could be persuaded to connect with them anything that is supposed to carry distinction in reference to the *scholar*, or acceptance in reference to the *gentleman*. Professors and students have been overwhelmed with a common obloquy, and the pretending buildings—brick in Corinthian form, covered with dirty London plaster—half done—and that half ill done—have been conceived pretty universally to represent faithfully the genius loci in all its aspects—governmentally, administratively, and educationally. Even those who thrive and do well on its funds—which are less beggarly than their results would imply—have no efficient advocacy to offer. All confess, that considering its founders, its aims, and its means, a more wretched failure has not outfaced the age. It is the great educational "folly" of the time.

An illustration of the hospital management of the University College people is furnished by a correspondent in another page. The narrative exemplifies how happily the managers succeed in frustrating the two objects of their institution—in *not* imparting sound information to their pupils, and in *not* preserving the lives of their hospital patients. The one circumstance uplifts any deceptive veil that may have interposed between the hospital functionaries inside, and their supporters outside, and shows in frightful clearness how the hand of charity may be perverted into the instrument of a curse by official shortcomings and ill deeds.

That the poor woman was killed by the hospital officials is a proposition that will bear no dispute. Suffering from illness, she applied to them for a cure: they gave her death. For skill she met incompetence, and for health she got the sleep that endeth not.

Now, was this catastrophe a mere accident? Did it originate solely from individual oversight? Unquestionably it did not. The hospital has been for months managed deliberately on a system to bring about such catastrophes as their inevitable result. The management has in view these dreadful occurrences. They are, if not *objects* and *aims*, most certainly necessary *effects*. The affair is *systemed* to produce them.

What are the facts of this extraordinary management? The pharmacy of the hospital is in the hands of a *pupil!* And what sort of a pupil? A *two year old student!* What are his previous qualifications? None. What are his opportunities of making his pharmaceutical *experiments*—for such they are—on the patients with some little carefulness and thought? Scarcely any—for he is going through the usual curriculum of study—pursuing the ordinary courses of professional lectures! He is too busy in learning surgery for the profits of another day, to be able to study pharmacy for the safety of the present. The neglect of his present duties is the *sine quâ non* for his fitness for the respectability of his future practice.

But he has assistance? Certainly. The pupils who are in the same position with himself, pay to be taught by him what he does not know. Costly sums are given as the title-deeds to a knowledge that does not exist. These high-paying, well-treated gentlemen *aid* their pupil-master in his pharmaceutical responsibility, adding to his ignorance the benefit of their own. In other words, the dispensing of the Hospital drugs is divided among half-a-dozen gentlemen, who, in the same way that Gil Blas' revered uncle learned to read his breviary in the process of teaching his nephew to spell, acquire the art of pharmacy by first essaying the perils of practising it. Instead of learning, and practising, and teaching, the Pharmacy Class of this Hospital have the novel system forced on them of teaching in the first place, and then practising, and finally of learning. The innovation is bold; that it is not quite safe, the death of the poor woman noted by our correspondent is monumental evidence.

But, apart from the pharmaceutical assassinations which this lax and barbarous system, or rather no-system, of medical attendance must be ever and anon perpetrating, what shall be said of the fairness—the propriety—the decency—the common honesty, of taking *large* fees for instruction in pharmacy, when the instruction is of the character we have under such painful illustrations adverted to? What is the explanation that can be offered to the deceived, the bubbled parents—or to an indignant public—both periodically appealed to on the Institution's behalf, as though its perfection out-paragoned belief? We say deliberately, that the tragical calamity we have recorded, originating in a system of management so palpably defective and wrong, throws a solemn responsibility on the rulers of this Institution; and that the public has a right to have vindicated, in the proper quarter, the injury and discredit it has thus ruthlessly been made to suffer.

AN UNFORTUNATE JOURNALIST.

ONE of our contemporaries—a medical journalist—has been indulging, very lately, in an angry lamentation, because deemed useless as an advertising vehicle, by the Committee of the National Association. The Committee called a meeting, and thought it useless towards getting a full assembly, to advertise in his journal. He is therefore not at all pleased that a hundred respectable and able Practitioners of the Metropolis and its vicinity, who know so well the *media* by which there is any chance of communicating with their professional brethren) think that the *Lancet* has now ceased to be worth the expense of an advertisement; and, very foolishly, he vents publicly in wounded rant the anger which this slight on his powers of publication provokes. One impolicy of this fit of grumbling consists in the fact that we are tempted by it to remind our contemporary of a pithy circumstance, very significant of the judgment and discretion displayed by the Association in their contemptuous neglect of him. *The Great Meeting of the "Associated Surgeons" was advertised in the* Lancet, *and not in the* Medical Times: THIRTEEN PERSONS *attended it! The Great Meeting of the National Association was advertised in the* Medical Times, *and not in the* Lancet, NEARLY ONE THOUSAND GENTLEMEN ATTENDED IT! If we would add one word more, on the question of journalist influence, it would be this:—the *Lancet* supported the "British College of Medicine" (the predecessor of Morison's), *and it is dead:* the British Association, *and it is dead:* the Medical Protection Assembly, *and it is dead:* the Princess's Theatre Association, *and it is dead:* the Committee (!) of "Associated Surgeons," and it is (if not dead, worse) *disgraced and routed.* Whatever it has opposed in the Profession has triumphed; whatever it has supported has failed. Our unfortunate contemporary, thus notorious to the public by want of influence as of circulation, must not be too sensitive to the slights of the advertising community, or he will have little else to do beyond the irritating task of resenting them. It has been sensibly said, that advertisements, the last things to come to a journal, are the last to leave it; with these impolitic murmurings, it is easy to see that our contemporary will soon be bereft of these—his last—supporters.

MISCELLANEOUS CORRESPONDENCE.

CASE OF POISONING AT UNIVERSITY COLLEGE HOSPITAL.

[To the Editor of the Medical Times.]

SIR,—I send you the following particulars of a recent case of poisoning in University College Hospital, with a few remarks on the internal *economy* of that institution:—

Ann Bridges, aged sixty-six, was admitted into the University College Hospital, under Mr. Quain, in the beginning of April last, labouring under gangrene of the right foot. She was placed in No. 5 ward, and did well up to the night of Tuesday, April 28th, the mortification being arrested, and the dead parts separating. It appears that on the night in question a draught containing three-quarters of a grain of muriate of morphia was ordered for her, as on two or three previous occasions. This was administered by the nurse of the ward, about nine o'clock, as usual. The patient shortly after expressed herself "very comfortable," and went to sleep. A little before 12 p.m., the night-nurse on duty was attracted by the patient's difficulty of breathing; she attempted to rouse her, but could not succeed, and in conse-

quence summoned the head-nurse of the ward, who immediately suspected the patient to be labouring under the effects of an overdose of opium, and called the resident medical officers. Some of th gentlemen immediately attended, and used every available remedy by means of stomach-pump, galvanism, &c., to save the patient, without success. She never recovered from her insensibility, but gradually sunk and died, about six o'clock on Wednesday morning, nine hours after the composing draught.

Vague rumours having got into circulation respecting this case, an inquest was summoned to be held at the hospital, before Mr. Deputy Coroner Mills, on Friday, the 1st of May, at the early hour of nine a. m., when the following facts came out in evidence.—

1. The draught ordered for Ann Bridges was taken by the nurse from a store bottle of solution of muriate of morphia kept in the ward. This solution ought to have contained one grain of the muriate to one ounce of fluid.

2. This bottle was emptied on the morning of Tuesday, the 28th of April, and was returned half full from the dispensary with other medicines on the evening of that day.

3. The nurse, who had been a resident in the hospital six years, had invariably, when any "anodyne mixture" was prescribed for a patient, measured the quantity ordered in a graduated glass, from the "store bottle," precisely as she did on this occasion.

Respecting the manner in which the medicines were dispensed, it appeared —

4. That the resident apothecary and the pupils of the hospital were in the habit of dispensing all the medicines indiscriminately.

5. That on this occasion the anodyne-bottle of No. 5 ward, had fallen to the lot of a young gentleman who, according to the house physician was "*very competent*" to perform the duty, "being a matriculated student of the university of London, and having officiated in the dispensary upwards of seven or eight months."

6. This very competent gentleman had, on this particular occasion half filled the "store bottle" of No. 5 ward with a strong solution of muriate of morphia, containing *one grain of the muriate* to *one drachm of fluid*, and consequently of eight times its usual strength.

It appears, therefore, that the patient, instead of getting three-quarters of a grain of morphia in the six drachms of anodyne ordered, actually took *six grains of the poison.*

The paid *apothecary* of the institution was not summoned.

The foreman of the jury returned a verdict to the effect that "Ann Bridges had died in consequence of neglect by the administration of an overdose of morphia." This did not appear to suit Mr. Mills, however, and after a little consideration, he so twisted the verdict as to make it an entirely different sentence, omitting the word "neglect." The recorded verdict, signed by the jury, ran, as well as I can recollect, as follows:—"That Ann Bridges, being a patient in University College Hospital, suffering under mortification, died in consequence of an overdose of medicine, accidentally administered."

Several of the jury expressed their opinions, in no measured terms, that there had been much neglect in preparing the medicine.

A few words on the system of dispensing in University College Hospital, and I have done. You will be astonished to hear, Mr. Editor, that a second year's student is the *paid apothecary* of this hospital, and that he is at the present time *attending lectures* in the college opposite. Under this gentleman are numerous pupils, resident and non-resident, who pay fees of considerable amount for the privilege of *being instructed* in practical pharmacy.

You will ask, perhaps, how it is that a student, *a licentiate of no examining body*, is the *paid* apothecary? My answer is, the apothecary's wages amount to *twenty pounds a-year, board and lodging extra*, less, by one-half, than those of any gentleman's valet. You will allow, Sir, that no man who has completed his education will undertake to dispense for upwards of two hundred patients daily for the pittance of twenty pounds a-year. Although, so far as I know, this is the first occasion on which so serious an accident has occurred in this hospital, I have been credibly informed that complaints have been before made, on more than one occasion, not only of the inefficiency of the dispensing staff, but of that of some of the under nurses, towards whom the same spirit of wretched economy prevails. On this subject I may, perhaps, again have occasion to address you.

By making the above case the theme of a few remarks from your own powerful pen, you will, I am sure, render a service to suffering humanity.

I am, Mr. Editor,
Your obedient servant,
MEDICUS.

P.S.—I enclose my card, for your own private satisfaction, in token of the good faith of this letter.

THE SURGICAL FELLOWSHIPS.

(To the Editor of the Medical Times.)

SIR,—In an editorial article of your last number, the surgical profession is informed, or at least a certain portion called M.R.C.S.'s, upon what terms they will soon be able to buy a fellow's degree from the College of Surgeons, and at so reasonable a price as to defy all foreign competition. The worthy councillors who watch over *their* interests are about to rival Sir Robert Peel on free trade principles— Hurra, then, for free trade! The Giessen market for M.D.'s will be undersold and annihilated, for, doubtless, a thriving concern will be established on its ruins, by the sale of fellowships, wholesale and retail, Lincoln's-inn-fields; and the accomodating Dr. Bond soon be numbered with the things of the past. Can you tell yet, Mr. Editor, whether there will be different orders of fellows? Because I would suggest if there are any unfortunates who cannot afford to pay—and being M.R.C.S.'s *of good character*, they cannot with justice be denied the *honour*—these, I think, should be admitted free and titled "*poor fellows.*" There may be others who are able but too stingy to purchase the *honour*, and this batch I would also enrol free, and designate in their diplomas "*shabby fellows.*" The men who fully appreciate the value of the distinction, and pay their gold like princes, and ever after look down contemptuously on *mere* members, ought as a distinctive mark worthy of them, to be placed on the highest pinnacle of collegiate fame, and be styled "*noble fellows.*" Other titles indicative of various degrees of *merit* might be prefixed to the fellowship, but these are merely thrown out as hints to be improved upon by the governing body.

I am, Sir,
Your obedient servant,
AN "ODD FELLOW."

March 31, 1846.

APOTHECARIES, SURGEONS, AND BARBER-SURGEONS IN THE OLDEN TIME.

The following descriptions of the apothecary, the surgeon, and the barber surgeon, taken from a work published in 1717, about a hundred years ago, and entitled "a General Description of all Trades," will be read with interest at present, as the subject of medical reform, and the status of the respective members of the profession, engage so much attention. It will be seen that exactly one hundred years since, in 1746, the surgeons obtained their separation from the company of barber-surgeons. In 1846, they seek indirectly to drive from their body corporate, the general practitioners. In their former attempt they in a measure succeeded; the present generation of pure (?) surgeons has a wiser and better educated class to cope with, and they will be ultimately foiled in their endeavour.

APOTHECARIES.—"This is a very genteel business, and has been in great vogue of late years, there being, as has been computed, upwards of a thousand in and about London. There are in this, and indeed in most other trades, various degrees as to employ and extent. Some do little else but make up medicines according to the prescriptions of the dispensatory (compiled by the College of Physicians for their direction) and those of particular physicians, besides visiting their patients. Others not only prepare almost all kinds of medicines, as well galenical as chemical, but likewise deal in drugs; with all which they supply their brethren in trade, and so become a sort of wholesale dealers, as well as apothecaries. Others again practise surgery, man-midwifery, and many times even officiate as physicians, especially in the country, and often become men of very large practice, and eminent in their way. There is also another branch many of them fall into, which is that of curing lunatics, &c.

"A youth, intended for this profession, should be a pretty good scholar, and have a tolerable knowledge in the Latin tongue at least if, not some in the Greek, that he may be the better able, in due time, to see the opinions of the ancients for himself, who mostly wrote in those languages, as have also divers modern authors in the first of them. Though, it must be owned, there are almost innumerable helps in our mother tongue.

"The sums given with lads, going apprentices to this business, are from £20 to £300 according to the reputation and station the masters are in. And if a boy is of an affable, acute disposition, genteel, and well behaved, it will be so much the better.

"They have no set hours for business; but I have observed they are not the earliest at it in the morning, yet attend pretty late at night. And an apprentice at first must expect to do the lower offices about the shop, though they generally keep serving men, or boys, to go on errands, and do dirty work.

"A journeyman has, according to his capacity, from £10 to £40 a-year, and his board.

"For a person, who may be inclined to set up, £100 may do; but £200, I apprehend, will fit up a smart shop; besides which they ought to have somewhat handsome to support them till they get into a good set of patients.

"Their shops are liable to the visitation of certain persons, called *censors*, who are four fellows of the college, and have power to inspect whether the medicines they keep therein are good, and to destroy those which are not so.

"In London they are one of the city companies, and were first incorporated with the grocers in the year 1606, in the reign of King James I., but not alone till 1617: Livery-fine £16.

"Their hall is in the Black-friars (where they have two fine laboratories, out of which all the surgeons' chests are supplied with medicines for the use of the Navy;) and their court-day is on the first Tuesday of the month.

"They have also a handsome barge, in which, being finely ornamented, with colours flying and music playing, they attend the Lord-Mayor to Westminster, on the day of his installation, when he goes to be sworn into his high office."

SURGEONS.—"This profession is attended with more or less expense in proportion to the sum that is required with the apprentice, and the place he is to reside in. In large and populous cities the expense is greatest; as the apprentice, during his servitude, is expected to make a better appearance; and the master enhances his demand, as the apprentice has better prospect of business from a multiplicity of acquaintance at the expiration of his time, and greater opportunities of improving his understanding and learning. There is no fixing the sum they take with an apprentice; for some have £50, others £100, and so on to £400 or £500, according to the reputation they are in. The expense an apprentice is at during the seven years, in furnishing himself with clothes, washing, and pocket-money, may be about £200. To furnish him with instruments, medicines, and proper books, £100 more. This, I believe, is the common expense of a surgeon that sets out in the midway."

BARBERS, OR BARBER-SURGEONS.—Of the mode of business, &c., of these, our author gives an account, after which he proceeds: "In 1512, in the reign of King Henry VIII., others having assumed the practice of surgery, they obtained a grant, that none, except duly qualified, should follow that profession. Then the barbers were restrained from performing any thing more in

surgery than tooth-drawing, and the surgeons from shaving.

"In 1515, in the same king's reign, they were, as surgeons, exempted from all ward and parish-offices, as well as military services.

"In 1541, the practice of surgery, which before had been restricted, was laid entirely open for any one to follow as should choose it.

"In 1746, the surgeons, being become populous, in great estimation, and most of them wealthy, began to claim the pre-eminence over their brethren the barbers, and wanted them to separate and withdraw themselves from their mansion; but they maintained their ancient privileges, kept their hall, and caused the surgeons to separate."

GOSSIP OF THE WEEK.

Apothecaries' Hall.—Gentlemen admitted Licentiates on the 30th of April, 1846.—Henry Thomas Hartnoll, James Yates, Joseph Hesslegrave, Francis Robert Hoghton, James Parett.

A Dr. Forster is said to be carrying on experiments at present to forward the growth of barley by means of electricity, and he is reported to have obtained from a part of a field on which he operated more than double the quantity of barley from the same amount of seed, to that grown in another part of the field, on which the electric agency did not act. The electric apparatus employed by Dr. Forster is very simple; he buries an iron wire in the soil at a trifling depth all round the field or part of the field on which he purposes to operate, and connects it at either end with another wire stretched in the air from north to south.

In the medical profession examples are not rare of the attainment of extreme old age; yet as a class they bear the visible marks of health below the average. The registration of one year may be an imperfect index; but the mortuary registration for the year 1839 having been examined, to ascertain what was the average age of death of persons of the three professions, it appears that the average age of the clergymen who died in London during that year was 59, of the legal profession 50, and of the medical profession 45. Only one medical student was included in the registration; had the deaths of those who died in their noviciate been included, the average age of death of the medical profession would have been much lower. *Chadwick's Supplementary Report on Interment in Towns.* Mr. Chadwick's statement in this report is in accordance with the statistics afforded by Caspar, of Berlin; who, however, takes the average age of human life at threescore and ten, and the average age of medical men at 45. This fact affords a striking commentary on the non-appreciation of the services of union surgeons by the poor-law commissioners, and some other authorities.

A proposal has been submitted to the King of Denmark by the academical senate to give a considerable increase of salary to those professors of the faculty of medicine at Copenhagen, who are willing to abandon private practice, and devote themselves entirely to teaching. The measure, if adopted, must be injurious, as the knowledge of the professors, if restricted from gaining experience by practice, must be principal theoretical; at all events, the experience they may have had previously to becoming professors, not being renewed by continued practice, will be lost to them, and the public will suffer by the withdrawal of good practitioners, whose place may not always be worthily supplied.

Dr. Ernest Cloquet, formerly one of the professors of the Parisian hospitals, has just left Paris for Persia, to fill the offices vacated by Dr. Labat, as physician to the shah.

The *Gazette Medicale* states that M. Obeuma, a Swedish physician, has started the idea of congealing people and then at some future time restoring them to life. Thirty people have already submitted to the process, and among them a very pleasing young woman, who was desirous of retarding the ravages of time for a few centuries. The doctor, enchanted at his success, proposed to the government to congeal the entire Swedish army, in order to save the expense of their rations, &c., until the soldiery were wanted, and he then pledged himself to restore them to service. In vain, however, did the learned doctor expatiate to the soldiery on the riches they would possess when restored to life, by their pay being reserved for them; in vain did he show them the bodies of twenty nephews who had suffered themselves to be frozen, in order that they might wait the more patiently for their uncles' inheritance; the excited troops revolted, and pursued the unfortunate doctor until he took refuge in one of his own ice-wells, where he was discovered the next day in a state of congelation. As his secret of thawing a man without danger is not known, it has been wisely decided to leave him in that state until the necessary information has been obtained. He bids fair, therefore, to remain congealed to the end of the world.

A. M. L. —— accused of practising medicine with a false diploma, was summoned to attend before the magistrate, and answer the charge. He refused to obey, and the gendarmes were sent to compel his attendance. When they arrived he was in bed, but rose at once, dressed, and wrapped himself up in a cloak as if prepared to follow the police; instead of which, however, he stabbed himself in the abdomen, and fell desperately wounded. When the gendarmes approached to render him assistance, he seized hold of an edge of the wound, and cutting off a slice, gave it to the brigadier, and said, "that's all of my body you will have to take to the king's solicitor." He was then placed in bed, and died soon after.

The Grand Seignior has recently ordered that the bodies of the female slaves who die in the markets shall be given up to the students in medicine for dissection. This is a great step in advance.

The government of Wirtemburg is adopting measures to diminish the amount of cretinism in that country. There are at present 2,901 cretins in Wirtemburg, being at the rate of one cretin in every 500 inhabitants; 1,193 of these are between the ages of fifteen and thirty years, 939 are more than thirty years old, and 769 under fifteen.

Plica polonica, it appears, is one of the diseases caused by a vegetable product. Professor Walther, of Kiew, on examining the matter which unites the diseased hair under the microscope, ascertained the presence of an infinite number of small round or oval corpuscles, having one or two nuclei in the centre, which seem to be the germs of other corpuscles. These researches confirm in a great measure those of Gunsburg.

South Staffordshire General Hospital.—The committee for managing the erection of this institution have accepted a tender to the amount of £8025, for the erection, the whole to be completed by Michaelmas, 1847. The furnishing, fittings, &c., will be ready by January, 1848, at which time it will be opened for the reception of patients.

Academy of Sciences, Paris.—M. Sedillot has just been elected a corresponding member of this institute, in the section of medicine and surgery.

Provincial Medical and Surgical Association.—The anniversary meeting of this society will take place at Norwich. The time is not known.

It is stated, in the *Gazette Medico-Chirurgicale*, that Dr. Arthault has invented a lithotritic instrument, by which he is able to reduce a calculus in the bladder to an impalpable powder in three minutes. He operated in this manner on a dead body at the Hopital Beaujon, in the presence of Dr. Laugier, Dr. J. B. Durand, Dr. Tavignot, Dr. Delaroque, jun., and Dr. Gariel, and was apparently entirely successful.

Royal College of Surgeons.—At the last meeting of the court of examiners of this college, the following gentlemen were admitted members, viz., Messrs. H. Gardner, S. Lowe, H. H. Harvey, W. P. Ward, A. Jowett, C. G. Ellis, H. Pritchard, J. T. Arlidge, and T. G. Wrench.

Dreadnought Hospital Ship.—The funds of this excellent floating hospital for the relief of seamen of all nations, have just been increased by a donation of 900 dollars, or about £190, from that enlightened personage Keying, the High Commissioner of his Imperial Majesty the Emperor of China. This munificent sum was presented through the hands of Rear Admiral Sir Thomas Cochrane, Naval Commander-in-Chief in China and India, to the treasurer of the hospital.

Appointments.—Surgeon: T. E. King, M.D., to the Constance. Assistant-surgeons, J. C. Buchanan, to the Constance; F. W. Sadler, to the Poictiers; Dr. Derriman, to Woolwich Dockyard.

Obituary.—On the 29th ult., at Cavan, Ireland, Thomas Heslop, M.D., late of Durham-row, Stepney, aged 40.

King's College.—We are happy to hear that a new hospital is to be built for this prosperous college on a new and very eligible site. The removal from the present locality—the hospital overhanging a crowded burying-ground—was early suggested by our indefatigable friend, Mr. Walker, who originated the public movement against intra-mural interment, and has been frequently and urgently called for in the pages of this journal. We congratulate the heads of the College, as well as the public, on the very salutary improvement. The College cannot but gain by it.

M. Tanchou, in a pamphlet published in defence of the electrical impostor, Angélique Cottin, refers the phenomena she exhibited to electricity, and he undertakes to prove that the *substitutions, chemical combinations, digestion, nutrition, respiration, the eliminatory functions, conception, and even the difference of the sexes, and the resemblance between children,* are all the results of electricity. We thought Faraday had carried the investigations respecting electricity and its powers further than any other observer of the present day, but his labours sink into nothingness beside the brilliant discoveries of M. Tanchou. Even Harvey himself appears a fool by the side of the French electrician.

Small Pox.—At a meeting of the Norwich Board of Health on Monday last, the Bishop of the Diocese in the chair, it was stated that the number of deaths from small-pox from September 1st, 1841, to March 1st, 1845, amounted to 266, and that it had been ascertained that one-eighth of the persons attacked with small-pox die. There was reason to believe, during the same period, no less than 2128 must have had the disease; it also appeared that, amongst the poor and destitute, one in seven attacked by the disease died, and, therefore, during the period above stated, there had been 1148 cases of small-pox among this class. This mortality, it was stated, was caused by the neglect of the parents in not availing themselves of the blessings of vaccination. From March, 1841, to February, 1845, inclusive, 1680 children of the poor had been vaccinated gratuitously.

MORTALITY TABLE,

For the week ending May 2, 1846

Causes of Death.	Total.	Average of 5 summers	Average of 5 years
All Causes . . .	831	892	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	123	162	188
Sporadic Diseases—			
Dropsy, Cancer, and other Diseases of uncertain or variable Seat . . .	79	98	101
Diseases of the Brain, Spinal Marrow, Nerves, & Senses	111	155	157
Diseases of the Lungs, and of the other Organs of Respiration	288	271	294

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

(From our own Correspondent.)

ACADEMY OF SCIENCES.

Meeting of the 4th May, 1846. M. MATHIEU in the Chair.

COMPOSITION AND NUTRITIOUS PROPERTIES OF COFFEE, BY M PAYEN.—M Cadet de Vaux and M C de Gassicourt fancied they had discovered in coffee gallic acid, a resinous substance, albumen, an aromatic essence, and mucilage; these substances present, however, only doubtful analogies with the well-defined elements of coffee Caffeine, discovered by Runge, and described by Robiquet, is a crystallisable and azotised body, easily sublimated into white brilliant crystals, and appears identical in nature with Theine, since detected in tea leaves Robiquet, besides, described with precision the effect of torrefaction on coffee The researches of Liebig appeared to show that coffee contained in reality but little or no nutritious matter; and M Payen, on the contrary, endeavours to demonstrate that the infusion of coffee contains several azotised principles, in quantity equal at least to ten times the amount admitted by Liebig; and that saline and fatty substances, of a nutritious nature, may also be therein detected According to M. Payen, the most remarkable of the immediate principles of coffee had not hitherto been discovered—a fact which is accounted for by the extreme facility with which that principle is altered by chemical operations Its most interesting alteration consists in the production of a fine green colour, which betrayed the presence of the unknown substance to M. Payen, and led to its separation in the shape of a white crystalline matter, which imparts a deep green hue to five thousand times its weight of water or alcohol M Payen has by experiment ascertained that torrefaction, according to its degree, removes from coffee 15 to 25 per cent in weight, and adds to its volume from 30 to 50 per cent. With regard to the nutritious properties of the infusion, M. Payen asserts that the infusion of 100 grammes of coffee in 1000 of water contains 20 grammes of nutritious matter, three times more than the same quantity of tea, prepared with 20 grammes to 1000 of water If milk be added to it, the result will contain six times more solid matter and three times more nitrogen than broth.

ACADEMY OF MEDICINE.

Meeting of May 5th, 1816; Dr. ROCHE in the Chair.

THE PLAGUE AND QUARANTINE QUESTION.

A letter was read from Dr. Aubert-Roche, communicating the intelligence received from Dr. Bowring, M P., that the House of Commons had ordered the translation into English, and the impression of the Report on the Plague

Another letter was read from Dr. Gaëtani-Bey, stating that in a conversation with Mehemet Ali, that prince had expressed much anger at finding that, notwithstanding all his efforts for the improvement of Lower Egypt, that province was still pointed at as the chief focus of the plague. After some discussion on the subject, the Pacha at last expressed himself convinced of the correctness of the assertion, and ordered that a sum of 50,000 purses be consecrated to the amelioration of the villages inhabited by the fellahs.

M. Prus then proceeded to read the practical conclusions of the Report on the Plague. The sanatory measures necessary to the security of France might be classed under five heads:—1. Indication of the countries from which the plague may be imported; 2. Precautions to be taken by ships leaving such countries; 3 Rules to be observed during their passage home; 4. Precautions to be taken on their arrival in French ports; 5. Measures to be adopted in case of the outbreak of the plague in France.

Sec 1.—The countries from which the plague may be imported are Egypt, Syria, and Turkey in Europe and in Asia. The regencies of Tripoli and Tunis, and the empire of Morocco, must also be attentively watched. It is not necessary that the sanitary precautions should be equally rigorous at all times of the year. Thus the fear of importation of the plague from Egypt into France may be almost altogether abandoned from the 1st of July to the beginning of November, experience having proved that the Egyptian epidemics have always broken out between November and February, and have always been arrested before the end of the month of June.

Sec. 2 - It is evident that those lands from which danger may be apprehended should be submitted to constant medical observation. For that purpose, French physicians shall be appointed to reside in the various countries in which their presence may be judged necessary. Their duty shall be to visit the ships in port, to return official information to government of the sanitary condition of the country, and to collect as many documents as possible relative to the plague. The above-named medical officers shall deliver a foul bill of health when a pestilential epidemic shall exist in their residence For all other cases the certificate delivered to the captain shall be a clean bill of health. The physician shall not only mention in the bill the sanitary state of the port from which the ship sails, but he shall, moreover, go on board, examine the passengers and seamen, and the hygienic conditions of the vessel; all which operations shall take place on the day previous to, or the very day of, weighing anchor. The permission hitherto granted to captains not to sail for six days after the delivery of the bill of health, renders that certificate perfectly nugatory. If it were true, as the researches of the commission appear to show, that the clothes and goods of pestilential subjects cannot communicate the disorder, it is evident that no peculiar measures need be adopted relative to them; but the commission is of opinion that in this matter it is best to act with due circumspection provisionally, and until further experiments have proved the innoxious nature of contaminated goods, they shall be ventilated during their passage home; or the trunks containing the clothes and linen of the passengers and crew shall be lead-lapped at the departure of the ship, and opened only in a French lazaretto.

Sec. 3.—All ships of the royal navy, and all the mail-packets coming from the Levant, shall have a physician on board, whose duty it shall be to keep a correct and circumstantial account of the sanitary condition of all persons on board, a special instruction containing the signs of the plague, its treatment, the measures best calculated to prevent the formation of centres of infection, &c., shall be placed by government in the hands of the captains of the ships unprovided with a physician.

Sec. 4.—On arrival in a French port, the bill of health and the diary of the physician shall be sent on shore and carefully examined by the medical officer of the port, who shall go on board, examine the crew, the passengers, and the ship, and report on their condition. The duration of the quarantine shall then be fixed by the competent authorities, after the examination of the bill of health, the diary, and the report. When the bill of health shall be a *clean* bill, and when the plague shall not have broken out during the passage, the quarantine shall last ten days from the date of departure. If the bill of health be a *foul* bill, the quarantine shall last fifteen days. The above regulations are applicable to the ships provided with a physician, all other ships furnished with a clean bill, and not attacked with the plague during the passage, shall undergo a quarantine of ten days from the date of arrival. The quarantine shall last fifteen days for the same ships, free from disease during the journey, but possessing only a foul bill, and the goods shall besides be landed. Any ship, whatever may be the nature of the bill of health, attacked at sea with the plague, or having on board at the time of arrival a patient affected with a complaint of a suspicious nature, shall undergo a quarantine, the duration of which shall be regulated by the sanitary authorities of the port. The crew and passengers of such ship to be confined in the lazaretto, for a period not exceeding twenty days, but not less than fifteen. The goods shall be landed and ventilated, the ship shall be cleaned, and must remain empty for one month at least; it shall be expressly forbidden to sailors, guards, &c., to go on board

Sec 5.—The patients affected with the plague have been hitherto treated in the lazaretto in a most unscientific and barbarous manner. The physician is forbidden to approach nearer than within twelve metres of his patient—a prohibition which the committee hopes in future will be raised. Other regulations, more in harmony with the rights of the patients and the feelings and habits of the physicians, must take the place of those rules hitherto in vigour, and which can no longer be permitted to exist. The commission proposes that all persons affected with plague, and received in a French lazaretto, shall be attended with the same care as the patients of our best hospitals. In case of death the bodies shall be dissected, and the minutes of the autopsy shall be signed by all present.

Sec. 6.—Should the plague accidentally break out in a French city, the patient shall be removed from the house of infection to a distant and well-ventilated place, where he shall receive the care he requires. The other inhabitants of the same house shall also be sent to another residence, where they shall be kept under the observation of a physician. The evacuated house shall be cleaned, and remain empty for the space of one month at least. Should several dwelling-houses be attacked, they shall be all treated in the same manner. The principle would remain the same if entire cities were attacked, and the measures above mentioned should be carried out with the utmost degree of severity.

ANATOMICAL SOCIETY.

Professor Cruveilhier in the Chair.

REPORT OF A CASE OF UTERINE TUMOUR CONTAINING ODONTOID OSSIFICATIONS; BY M. PIGNE.—If the ossifications under consideration be genuine teeth, the case must be one of extra-uterine pregnancy, or one of deformity of twins by intussusception. We will endeavour to prove that it belongs neither to the first nor yet to the second morbid degenerations, and that it is simply an ossified fibrous tumour. The cases of extra-uterine pregnancy described by authors, those contained in the collection of the Musée Dupuytren, and those which have fallen under our own personal observation, are 84 in number. In 15 of these cases, the fœtus had ceased to live so short a time before dissection, that none of the organs were modified in appearance by death. These 15 instances cannot therefore throw any light on the present preparation, and we must set them aside. In the 39 others the embryo or fœtus was 8 times desiccated, 7 times petrified, 4 times surrounded with a hard, solid crust, and 20 times in an advanced state of decomposition. 1. In the 8 cases of the first class the bodies were mummified, but had preserved their shape; the fluids had been taken in by absorption, and the solid parts had become porous and friable. The integument had the colour of parchment, and was perforated with numerous apertures of various size; all were contained in a thick cyst, frequently cartilaginous and sometimes ossified. 2. In the 7 instances of petrifaction of the fœtal body, it was completely saturated with calcareous salts, but had preserved the external forms of the human subject, being also enclosed in thick cysts. 3. The cases of the third class are perhaps the most interesting; of these four cases, the first had sojourned nineteen years in the maternal peritoneum, and was on all sides surrounded by a semi-calcareous and semi-ossified cyst. The full-grown fœtus was in a state of perfect preservation, and had not even lost the natural colour, flexibility, and elasticity of its parts. The brain was changed into a butyraceous mass, identical with fatty matter, and containing that substance first pointed out by Vauquelin, and called by M. Couerbe cérébrote. The same remarkable state of preservation was observed in the case related by Walther, in which the fœtus remained twenty-two years in the abdomen, in the fœtus observed by Camerarius (forty-six years), and in Nebel's case, in which the fœtus had been encysted fifty-four years. 4 Cases of putrefaction of the fœtus are too well known to make it necessary for us to insist upon the description of their characters. The tumour which has occasioned this report does not come under any one of the above divisions, and cannot therefore be referred to extra-uterine pregnancy. We cannot consider it with more propriety as one of gemellar intussusception, in which teeth or hair are often found. These tumours are always surrounded with a thick cyst, and contain a quantity of fat, in which are imbedded the teeth or hair. In the same cyst the *hairs are always of the same colour*. Their length may be considerable, and attain two feet, as observed by Blumenbach, or even three feet, as in a preparation of our museum. The teeth contained in such tumours are usually three or four in number, and sometimes more; they are well formed, and usually adhere to the cyst. Portions of bone (maxilla, face, pelvis, limbs) are occasionally detected. These tumours are not always situated in the abdomen, thus 72 instances have been published, 43 occupying the ovaries, 14 the peritoneum, 7 the testis, 3 the thorax, and 5 being attached to the arch of the colon. Such tumours appear to exist more frequently in the female than in the male subject; thus of the 72 cases above mentioned, the tumours were found 49 times in girls, and 23 only in boys. This difference cannot be attributed to confusion between gemellar intussusception and extra-uterine pregnancy, for many of these tumours were removed from the bodies of children; 5 were found in children not twelve years old; 6 in girls under two years; 4 in female infants stillborn, and 2 in fœtuses born one month before their time. In these cases it is quite evident that the monstrosity must be attributed to the reception of one child in some part of the body of its twin sister or brother. The teeth observed in such tumours are also always found to belong to first dentition. The portions of bone are arrested in their increase of size, but have continued their ossification; the epiphysary lines have disappeared, and their eburnation is perhaps more complete than that of the adult bone. How can we account for the formation of such tumours? The reporter is of opinion that the following theory is the most correct: On examination of a large number of ovaries, one at least in every ten will be found containing Graafian vesicles so closely united together that the two cavities communicate with each other. Now one of these vessels cannot well be impregnated without its fellow being so at the same time, and both ovules must grow together united in *one* common envelope. But if the development of one germ progresses with more rapidity than that of the other, the latter will inevitably become incarcerated in the first developed orga of the former—i. e., the heart and the corpora Wolfiana, which preside more particularly over the formation of the ovary, testis, and colon. In these organs, therefore, will the reception most commonly take place. This was the opinion adopted on the subject by Dupuytren, Osann, and Prochaska; Hufeland refuses to admit it. The case presented to the Society presents none of the characters belonging to the tumours we have described; it is an ossified fibrous tumour of the most common description, and it is a matter of some surprise that any doubt should have ever been entertained as to its real nature.

HOSPITAL NECKER.

CLINICAL LECTURE ON DIARRHŒA OF INFANTS; BY PROFESSOR TROUSSEAU.

The influence of the change of seasons is very strongly felt in hospitals destined to infants. During the course of the winter a numerous series of pulmonary and cephalic disorders has passed before us; we are entering now into spring, and the coming heat will bring with it intestinal affections. Soon, perhaps, you will not in one month meet in these wards with a single case of pneumonia, twelve or fifteen cases of which were admitted during every month of the winter. Thoracic diseases will be replaced by abdominal symptoms, and amongst these diarrhœa being the most frequent, the most difficult to treat properly, and the least understood, we will endeavour to prepare you beforehand for its observation by some remarks upon its pathology and treatment. The subject is extremely difficult, and although I have for eight years devoted myself to a daily study of the maladies of infancy, I feel myself in the dark with regard to many of its details, and do not therefore pretend to give you a completely satisfactory description, but merely to impart the little I do know of the matter. In order to introduce some regularity in the following remarks, we deem it necessary to establish a practical division between the various sorts of diarrhœa which are observed in children. We acknowledge only four primary forms of diarrhœa. 1, diarrhœa; 2, mucous diarrhœa; 3, lienteric diarrhœa; and 4, choleriform diarrhœa, or cholera infantilis. These forms are perfectly distinct from each other, and all the varieties of diarrhœa which may be observed in children, and which do not seem at first to have a place in our classification, will be found to consist of combinations of several of these original forms, or of deviations from these elementary types.

Causes.—Bilious diarrhœa may consist in a simple increase of the biliary and pancreatic secretions, or in a perversion of their qualities. Both may result from local irritation, but the first is often produced by mere physiological excitement. We will find a double illustration of these pathogenic influences, in the abundant flow of saliva determined by stimulation of the mouth with mercury, and in the increase of the secretion of tears caused by sorrow. Thus, slight inflammation of the stomach or duodenum will occasion a discharge of bile into the intestine; thus fear, anger, nervous excitement, in a word, will also produce an increase of the biliary, pancreatic, and sometimes the renal secretions. We may say we meet with daily examples of the great power of physiological stimuli on the conglomerated glands. The diarrhœa of the young soldier who goes into action for the first time, is another common instance of the same kind, a further illustration of which we find in the influence of dreams on the spermatic organs. Violent exercise, abundant perspiration in many persons bring on diarrhœa. In the water-cure, a method of treatment too advantageous in some diseases to be entirely left to quacks, we find that during the process of packing, if the patient is made to drink several tumblers of water, abundant perspiration is thrown out, but if diaphoresis does not appear, the mucous surface of the intestine substitutes its action to that of the skin, and relieves the system by diarrhœa. One of the most frequent causes of diarrhœa will be found to reside in the quality of the food. The presence of globules of colostrum in the nurse's milk, due, as Donné has proved, to latent irritation of the mamma, sudden weaning, the exhibition of improper food, are all circumstances by which diarrhœa may be occasioned in the infant. The habit of covering the child in bed with too warm clothing, is also a frequent cause of disease. This is unfortunately a habit very prevalent amongst the lower classes in this country. So many as four blankets are thrown child, who is besides enveloped in swaddling clothes; and to add to the child's comfort, the mother not unfrequently adds her pillow to his other clothing. Abundant perspiration is thus produced, and, without any regard for the consequences, the child is extracted from his bed to be suckled or cleaned, thus being exposed several times a-day to sudden changes of temperature, the result of which is pulmonary disease in winter, and intestinal derangement in summer.

Semeiology.—Bilious diarrhœa generally follows slight feverishness, and is often preceded or accompanied by vomiting. The mouth is bitter, the tongue foul, and the appetite absent. The colour of the motion varies from yellow to green, according as the biliary secretion is changed in its quality, or only increased in quantity. Its duration is from three to six days, and its termination favourable, unless the case is mismanaged. It is in fact a slight catarrhal condition of the mucous surface. Mucous diarrhœa is marked by the discharge of a new secretion from the bowels; it is often the consequence of the first variety of disease, or of indigestion. The nutriment acts as a foreign body upon the intestine, producing local irritation, and the excretion of a slimy mucus. This is a very common, and fortunately not very dangerous form. But when the irritation of the digestive tube is carried beyond certain limits, matters take a more serious aspect; enteritis sets in, and the products of inflammation are passed with the motions. Colitis occasionally makes its appearance, attended with intense pain, betrayed by cries uttered two or three minutes before the motions, with which a small quantity of blood is sometimes mixed, the dejections assuming a dysenteric character. When the small intestine alone is inflamed, our third form of diarrhœa, lientery, appears. In this variety the food passes unaltered through the digestive organs, and is recognisable in the dejections, in which grains of rice, vegetable substances, curdled milk, can be readily distinguished. This is an extremely dangerous derangement, on account of the impossibility of refection.

After one of the above kinds of diarrhœa, occasionally without them, the cholera of children—that almost invariably fatal affection—is observed to show itself. After dejections of a bilious or mucous character, the infant is suddenly seized with violent vomiting, against which the efforts of ar

remain unavailable. A watery diarrhœa of a greenish hue is at the same time discharged from the bowels, and alarming general symptoms are noticed. The eyes sink in the orbits, the features are decomposed, the complexion becomes livid, and the nose tongue, extremities, and even the breath, grow cold; the cry is acute, small, and incessant; the skin loses its elasticity, and when pinched in any part of the body, retains the folds made by the fingers, as if it were become an inert membrane. The child is sleepless, but without convulsions. Such are the first symptoms of this formidable malady. In its second period the vomiting, and sometimes the diarrhœa, cease, but no amendment follows. The collapse increases, and the infant almost invariably dies. We have, however, occasionally had the consolation of saving some few cases; one is at present in the wards, to whose case we called your attention, and who owes his recovery, under Providence, to the double tartrate of soda and potass.

Treatment.—We have found few drugs of any avail in the treatment of the bilious diarrhœa in children. It is a convenient plan to call the malady a gastro-enteritis, because the denomination leads to an invariable line of treatment, accessible to understandings of the meanest capacity. We take, however, a different view of diagnosis generally, and deem it unprofitable unless it leads to some practically useful indication. Some forms of diarrhœa are doubtless less difficult of cure than others, but we must say that the varieties we have described often combine with each other, so as to cause the practitioner no small embarrassment, and to reduce him, in many cases, to a blindfold empiricism; not but that we profess much respect for that empiricism which teaches us to exhibit mercury in syphilis, steel in anæmia, and bark in ague; but the empiricism we deprecate as a contemptible method is that which is not guided by diagnosis. The method we refer to may become a useful guide to the detection of the nature of disease, and it then acquires a considerable degree of utility. Let us remind you of a case of hemicrania at present in the wards. The attacks were periodical, and we tried sulphate of quinine without success; thus acquiring the knowledge that it was not governed by miasmatic influence. We exhibited then mercurial preparations, and the nervous headache having yielded at once, we were led to attribute the disease to syphilis. This is the empirical method we adopt, it is not the empiricism of *experiment*, but of *experience*. Thus, if we say that a patient is affected with neuralgia, we express a diagnostic opinion which is as elementary, and, let us add, as useless, as to say that he is affected with a corn on his foot; but it is quite another sort of thing to say that the patient is labouring under gouty, syphilitic, miasmatic, rheumatic, or chlorotic neuralgia, because this kind of diagnosis leads us to the real therapeutic indications. To return to the treatment of diarrhœa. Let us not forget that, to arrest the superabundant intestinal secretion is not by any means to cure the complaint which caused it. It is our opinion that bilious diarrhœa is only a very superficial catarrhal derangement of the intestine. The most efficient treatment consists in the exhibition of neutral salts, such as the double tartrate of potass and soda, phosphate of soda, Epsom or Glauber salts. We do not wish you to understand that we recommend the use of purgatives. No; castor oil and magnesia, or manna, you will usually find unsuccessful, whereas the neutral salts generally produce a speedy amendment. We have also derived benefit from the exhibition of the pulv. ipecac, at doses varying from two to ten grains, and mixed with a little jam, milk, or simple syrup. The action of this medicine is threefold: it is a substitutive, a discutient, and being a diaphoretic deviates towards the skin those vital energies which are occupied in the production of morbid symptoms in the alimentary canal. But when the bilious diarrhœa is the consequence of mere nervous excitement—when it is caused by fear or anger, as tears by grief, or salivation by appetite—opium gives relief in a very short time. In these cases, which you will find to be characterised by the absence of any sort of suffering during the first twenty four or thirty-six hours, the disease will speedily yield to the influence of hypnotic medicines. Half a drop of Sydenham's laudanum is a sufficient dose for a child under six months; others, it is true, will bear two or three drops, but that dose is too powerful a narcotic for the many. The laudanum should be dissolved in an ounce mixture, whereof the infant shall take a teaspoonful every three or four hours; but when the disorder has lasted beyond the specified time, opium ceases to possess its salutary effect, because the mere presence of the increased secretions on the mucous surface has sufficed to bring on an irritation which did not exist at first. Then we must again have recourse to neutral salts.

In mucous diarrhœa we have generally derived benefit from three sources saline purgatives, calomel, and rhubarb. The dose of calomel we recommend is one-fifth of a grain daily, mixed with half a drachm of sugar. This should be continued two or three days at furthest. As to rhubarb, it is the "syrup" we use, the so-called "sirop de chicorée"—a good preparation in everything but its absurd name, which insinuates the idea of the efficacy of the endive, which is, on the contrary, perfectly inert. Great attention should be paid to the child's diet; his food, less abundant than usual, should be chosen with great care. Milk is the most proper food for young children; fecula and broth also may be given after the expiration of the first year, and the drink should be in small quantity. In the choice of food the physician must also allow himself to be guided, in a great measure, by the idiosyncracy of the child, and the mother's remarks on the peculiarities of his appetite.

DAN. M'CARTHY, D.M.P.

Spain.

ANATOMICO-PATHOLOGICAL OBSERVATIONS UPON PHTHISIS.

By D. José Seco Baldor.

(Continued from page 92.)

CASE 7.—*Chronic Inflammation of the Pleura and Peritonæum, with Tubercles in both Membranes. Calculous Tubercles in the Lungs. Bronchial Glands Tuberculous. Acute Encephalitis.*

On the 17th of July, 1837, a soldier, in a state of great weakness and emaciation, was received into the Hospital of Saint Isabel. He complained of severe pain in the head; and exhibited signs of mental perturbation. On the morning of the 18th, he was found in a state of perplexity. He would answer no questions, and was occupied in rummaging the cupboard connected with his bed; and paid no attention to the attempts which were made to restrain and quiet him. The pulse, examined with difficulty, indicated no fever. Diet of rice; a demulcent decoction; twelve leeches behind the ears; blisters to the lower limbs. Evening, no better. Blood drawn by the application of two cupping-glasses from the neck.

19. Patient tranquil; but continued speechless and inattentive. Commencement of general paralysis. Laxatives, of antimonial wine.

20. Countenance destitute of expression. Eyes fixed, or moving involuntarily; pupils dilated, and, at times, immoveable. Diminution of the sensibility of the skin, and organs of vision, hearing, and smell. Paralysis of the muscular system, general, and equal in both sides of the body. Position supine; difficulty of deglutition; loss of speech, from morning of 18th. Bowels constipated, even with the antimonial wine. Evacuation of urine involuntary and unconscious. No distension of the hypogastrium. Pulse slow and weak. No increase of cutaneous temperature; hands and feet cold. Respiration slow, and, although obscure, perceptible in every region of the chest, which sounded, with natural clearness, on percussion. Sinapisms applied, in rapid succession, to the lower limbs and abdomen; blister to the nuchal region. Two grains of emetic tartar, in six ounces of *aqua melissæ*, and one of syrup of gum, to be administered by spoonfuls.

21. Less paralysis. The patient answered not, when spoken to; but opened his eyes; and once put out his tongue, which was clean, without deviation to the right or left. He raised, himself, both legs and the right arm, and both arms, having been elevated, sank by degrees, and not like inert bodies, as happened on the preceding day. Deglutition better. This morning the patient replied to the nurse by signals; but not during the physician's visit. The antimony had moved the bowels, and produced nausea. The blisters had taken effect; and the sinapisms imparted to the skin a livid-red colour, like that seen in typhoid patients, and in the depending parts of the dead body. Pinching excited no sensation. From the evening of this day, he continued to grow worse, and died at five o'clock on the morning of the 23rd.

NECROTOMY, THREE HOURS AND A HALF AFTER DEATH.

Head.—General induration of both cerebral hemispheres, with hyperæmia of the medullary substance, evidenced by the bloody points seen in it upon incision. Corpus striatum softened in the second degree, that is, in a manner appreciable by the eye, and of a reddish-grey colour. Half an ounce of serum in each lateral ventricle; the vessels of which were extraordinarily injected. The cerebellum, mesocephalon, and bulb of the spinal chord, not indurated.

Thorax.—Left pleura in a state of chronic inflammation. Tubercles in it and the right lung. Those of the lung hard, calculous, and more abundant in the vertex than the other parts. The bronchial glands of both sides semi-tuberculated. Bronchial membrane sound.

Abdomen.—Peritonæum red, inflamed, and exhibiting tubercular granules, of a fatty appearance. The omenta red, as well as very thick, and converted into a hard, in some parts, yellowish and fatty substance. Urinary bladder empty, dilated, and directed upwards.

REFLECTIONS.

This patient could supply no dates respecting the disease for which he had been admitted into the hospital, nor the chronic ailments whereby his state of marasmus had been induced. From the first visit, it was manifest that, in addition to the acute disease which affected the head, there existed some other, of chronic and formidable character. This was demonstrated by the dissection; which, at the same time, proved the existence of acute inflammation of the brain, indicated by the symptoms which the patient had previously exhibited.

We have, here, another example of tuberculous secretion in the pleura, consequent upon inflammation of that membrane, with the remarkable fact of the existence of a similar lesion of the peritonæum, resulting from a like cause. From the calculous hardness of the pulmonary tubercles, it may be inferred that they existed previously to the occurrence of the pleurisy and peritonitis. On the other hand, there is no other cause (than inflammation) to which they can be reasonably attributed, for, had they been of constitutional origin, they, instead of becoming calculous, would have continued to develope themselves in much greater number; and, after a certain time, part of them would have softened. As the patient came to the hospital in a state of exhaustion, and could give no information respecting his constitution or ailments, it is impossible to ascertain, with certainty, the origin of these tubercles, or that of the incipient tuberculization of the bronchial glands. No inflammation of the bronchial membrane existed to explain the development of this glandular lesion.

In this case, percussion and auscultation availed nothing. The reason of this was made obvious by dissection. The quantity of fluid effused into the pleura was too small to impair the respiratory murmur, or alter either the voice, or the sound of the thoracic parietes. The tubercles, moreover, were few in number, and widely scattered; and the parenchyma of the lungs sound. To this may be partly attributed the absence of cough. For, although not suffering from catarrh, the patient would have coughed if there had been many tubercles, and the pulmonary parenchyma had been, to a certain extent, obstructed.

CASE 8th.—*Chronic Inflammation of the Right Pleura, of the Bronchia, Pericardium and Peritonæum. Acute Inflammation of the Left Pleura. Tubercles in the Heart, beneath the Pericardium. Bronchial Glands tuberculated.*

A soldier was admitted into the Hospital of Saint Isabel, with pain in the breast, cough, thick mucous expectoration, dyspnœa, obtuse sound of all the posterior part of the right side the thorax, and

the inferior half of the anterior and lateral parts; but, elsewhere, clear. Respiration was, everywhere, perceptible, but obscure where the sound was dull. Mucous *râle* not very strong, in both sides. Pulse frequent; skin hot; evening-accessions of fever. Appetite impaired; thirst during the febrile paroxysm. Belly constipated, with occasional pains; nausea; vomiting; paleness of skin; debility; incipient marasmus.

The condition of the patient grew gradually worse. On the 7th of January, 1837, he was attacked with violent pain in the left side, and great dyspnœa. Pulse very quick, with loss of voice. Death in three days from the exacerbation.

NECROTOMY, ON THE MORNING OF THE 11TH.

Thorax.—The right costal and pulmonary pleura thickened, white, opaque, and covered with thick pus. More than a pint of clear pus in the corresponding cavity. Lung compressed by the fluid, but not inflamed. Left costal and pulmonary pleura, in many points, injected with blood; in others, covered with thick pus, or, rather, with purulent clots. In the cavity of this side, more than half a pint of transparent serum, with flakes of coagulated pus floating in it: the lung sound. The glandular bodies which surround the bronchia and larger vessels, increased in volume, and tuberculated. The bronchial membrane injected; exhibiting in various parts, spots of a dull-red colour, and covered with mucus like that which the patient had expectorated.

Heart and pericardium adhering together, so as to form one body. Indurated tubercles over the whole surface of the parenchyma of the organ, between it and the serous membrane by which it is invested. No tubercle in the substance of the lung.

Abdomen.—The whole peritoneal cavity, of a dusky colour, and extremely fetid. The different portions of the membrane adhering together, so that the viscera formed one body united to the abdominal parietes.

REFLECTIONS.

In this case, one mucous, and three serous membranes were the seat of chronic inflammation. The condition of the pleura, bronchia, and peritoneum, were recognized during life; but the inflammation of the pericardium was discovered only by dissection. This revealed, also, another lesion, the existence of which could not have been previously suspected:—the tubercles developed on the surface of the heart, beneath the (adherent) pericardium, doubtless, the result of pericarditis; as the tuberculated condition of the bronchial glands had been of bronchitis: for, had the tubercles been of a constitutional and primitive character, some would have been developed in the lungs or other organs, and not in the heart, where they are very rarely met with, even in those cases of tubercular diathesis, in which they are simultaneously developed in several organs of the same subject.

CASE 9th.—*Obstinate Quotidian Fever; Peripneumony; Bronchitis; Crude Tubercles in the left Lung.*

A soldier, belonging to the 17th regiment of the line, married, adult, of dark complexion, and well-constructed thorax, entered, April 16th, 1833, into the Military Hospital of Mompellier. For nineteen months, he had suffered from quotidian intermittent; which, yielding to no treatment, had greatly weakened and emaciated the patient. His skin was discoloured; his muscles flaccid. Every evening, the fever returned, with much flushing of the face, and severe internal pains, particularly in the left hypochondrium. This was considerably elevated by the extraordinary volume which the spleen had acquired.

For some days, no medicine was prescribed, but, at last, the sulphate of quina was administered with benefit. The paroxysms were more slight, the spleen diminished in volume; and everything conspired to induce a favourable result when, at the beginning of May, the patient was attacked with cough, dyspnœa, and continued fever. The quina was laid aside, and, on the 11th, sonorous and sibilous *râle* were detected, by auscultation, in the whole of the left side, and in the posterior and lateral parts of the right. Infusion of borage, with honey, a gummy potion: a blister to the left side.

From the 11th to the 16th, the dyspnœa greatly encreased. The patient experienced anxiety, suffocation, a sense of heat and oppression in the præcordial region, and invariably reclined upon the left side. Great thirst; and utter repugnance for food; and, on the 16th, profuse diarrhœa. On auscultation, the respiratory murmur was perceptible over the whole of the left side, except the internal part of the sub clavicular region; and bronchophony was clearly observed. The sound, on percussion, very dull, or utterly extinct, in the whole side. In the posterior part of the right, there were sonorous and crepitous *râle*, which somewhat obscured the respiratory murmur. In the remnant of this side, respiration was puerile; the sound clear over the whole. Milk-diet. Another blister to the left side.

17.—Crepitous *râle* in the left posterior region, with diminution of the dyspnœa. But profuse diarrhœa succeeded, with very frequent puls, and burning skin. Twelve leeches to each side of the thorax.

18.—The patient continued to recline on the left side, without being able to lie upon the right, from a sense of suffocation. Cough troublesome, with expectoration of a clear and slightly frothy sputum. Pulsations of the heart, strong, frequent, but circumscribed. Pulse (at the wrist) frequent, and almost filiform. Lancinating pain in the right axilla. Four cupping-glasses applied to that region; and six grains of squill with three of *digitalis purpurea*, made into four pills.

19.—Pain relieved. Respiratory murmur augmented in the whole right side, and in the internal part of the left sub-clavicular region; extinct in the remnant of this side. At three, p. m., great anxiety, orthopnœa upon reclination on the left side. Excessive heat, with profuse perspirations. Pulse very quick. Eight ounces of emulsion.

20.—Crepitous *râle* in the lateral and posterior part of the right side. Expectoration bloody, and more abundant than on the preceding days. Other symptoms unaltered.

21.—Crepitous *râle* in the right anterior and lateral parts: respiratory murmur extinct in the posterior. From this day to the 28th, the dyspnœa, sense of internal heat, thirst and diarrhœa, were aggravated. Pulse invariably small and very quick. Skin perspiring; and patient reclining on the left side. Death at nine on the morning of the 28th.

NECROTOMY, TWENTY-THREE HOURS AFTER DEATH.

Exterior.—Marasmus in the first stage.

Thorax.—Hepatization of the whole left lung, except the anterior border which was sound; and certain other small and ill defined portions, which, although affected with hyperæmia, were yet crepitous. The parts most hepatized, were the base and posterior border, and these contained some crude tubercles. The posterior half of the right lung also hepatized, especially below. anterior portion partly sound, and partly hepatized in the first degree. Both lungs strongly adherent to the diaphragm and ribs. Their root enveloped in a mass of enlarged, indurated, and dark-coloured glands. The bronchial mucous membrane red, wherever examined. Eight unces of yellow serous fluid in the pericardium. Heart flaccid and distended with coagulated blood in its cavities and larger vessels.

Abdomen.—The liver and spleen somewhat voluminous: surface of the latter corrugated. Left kidney double the size of the right; convex behind, and somewhat flattened anteriorly. Divers of the mesenteric glands, of the volume of a nut, and of ardaceous aspect and existence. The gastric mucous membrane generally pale, but, in some points, of a red or livid colour: the duodenal dusky. That of the jejunum and ileum, in five sixths of its extent, superiorly, of a slate colour bordering, in some points, upon violet: in the lower sixth portion, pale and sound. Cœcum much injected, and of a dusky-red colour. This injected state existed, also, in the colon; but gradually diminished as it approached the rectum.

REFLECTIONS.

In the last six cases, tubercles were found to have been developed in consequence of inflammation of the pleura, both in the pleura itself, in the false membranes,—the product of inflammation,—and in the pulmonary parenchyma. In the present case, the tubercles, discovered in the left lung, were, doubtless, the result of the inflammatory process: and the only difference is that here the lung constituted the principal seat of the inflammation, and, in the preceding cases, the pleura.

The cause of this pneumonia was apparently the prolongation of the intermittent fever. In the history of the chronic phlegmasiæ, other analogous cases may be cited which prove, like this, the importance of cutting short the febrile accessions, in order to avert the sanguineous congestion which, during their invasion, frequently attacks the viscera.

Once developed, the inflammation of the left lung travelled to the right lung, and corresponding pleura: and thus destroyed the patient, while the tuberculization was yet in an incipient state. Dissection confirmed the existence of inflammation in both lungs, and of sanguineous congestion, if not real inflammation, in the spleen, left kidney and liver, resulting from the same cause which had produced, in these organs, a notable increase of volume. The enlargement of the spleen seemed to diminish as the (febrile) accessions subsided, and, in fact, the rugæ discovered in its fibrous membrane, and the flattened condition of the anterior surface of the left kidney, proved that the spleen had, formerly, been more voluminous than it was found in the dead body.

(To be continued.)

England.

DISEASE OF THE MITRAL VALVE.—Mr. Russell, jun., describes the case of a man who had symptoms of heart disease for eight years. For the last three months the dyspnœa was extreme, and he could only breathe by placing himself on his knees and elbows, so that at last his elbows became quite sore. Before his death serum was effused universally and into the cavities. Dr. Fletcher examined him once, some time ago, and states that he then heard a rough bellows sound, most intense in the situation of the aortic valves, accompanying the first sound of the heart, and very superficial; but the sound did not extend up the course of the aorta, he was therefore puzzled to form a diagnosis, but thought there was either disease of the aortic or mitral valves. From the position assumed by the man, aneurism was expected. There was regurgitation into the veins of the neck. On examination, the veins were found very large; the lungs much condensed; no other disease excepting in the heart. All its cavities were distended with black blood, as were the veins and the aorta, to such an extent was the aorta loaded, that it was at first mistaken for the vena cava. Both the auricles were large, and their walls increased in strength; the superior vena cava was large; the right ventricle was dilated, and the walls were nearly double their healthy thickness; the left ventricle somewhat dilated, but not hypertrophied; the tricuspid and pulmonary valves healthy, excepting that the latter seemed even thinner than natural; the aortic valves were healthy, excepting that at the origin of those two which are connected with the flap of the mitral valve, there was a rim of firm half cartilaginous matter. The mitral valve was diseased; the disease seemed to consist in a deposit of very firm almost cartilaginous matter at the free extremity of the flaps, extending to the tips of the columnæ carneæ, matting together the chordæ tendineæ, which might be seen emerging in a healthy state from the upper portion, and spreading on the valve, and by coalescing from each valve, reducing the orifice to such an extent as only to allow the tip of the little finger to pass through. The flap towards the septum was quite healthy, glistening, and smooth, though thicker than usual; the other flap was more invaded by the disease, which might be felt terminating on it, by its thick edge; the flap was much shortened, but the chordæ were free, unlike those of the other flap, and quite healthy, though short. The lining membrane of the left auricle was opaque, but smooth, more particularly that of its outer wall. All the other cavities were quite healthy.

CARCINOMA OF THE RECTUM.—Dr. Fletcher describes the case of a female who died from carcinoma of the rectum, complicated with the same disease in the liver. On examination of the body the heart was found healthy; in the lungs there were cicatrices at the upper portions, and general adhesions of the pleura. Eight or ten nodules of carcinoma were found in the liver, varying from the size of a hazel nut to that of a large walnut

the pancreas and spleen were healthy; the stomach was healthy; the small intestines were distended and the large intestines very much so down t about the upper part of the middle third of th rectum, where the distention ceased abruptly, and where the intestine was found hard and contracted The disease occupied about the middle third of the rectum, where the coats were much and irregularly thickened, and the capacity reduced, so as to admi with difficulty the little finger to be passed into it Dr. Fletcher remarks that the cause of the complete obstruction in this case, as in other cases of mecha nical obstructions he had seen, was as much from the distention of the intestine above the contraction causing a valvular closing, as from the contraction itself.

Colchicum and Tobacco in Cardiac Neuralgia.—Dr. Fife, in the *Provincial Medical and Surgical Journal*, says that in cardiac neuralgia, he found colchicum especially useful, either with or without a few drops of the tincture of digitalis with each dose, when the action of the heart was much increased as well as irregular. A local application, in these cases, of great efficacy in relieving both the inordinate action and intense pain, is the tobacco leaf, slightly moistened and placed over the region of the heart, care always being taken to remove it so soon as any feeling of giddiness, faintness, or sinking, is experienced by the patient.

Malignant Disease of the Eye.—Mr. Page describes, in the *Provincial Medical and Surgical Journal*, a case of malignant disease of the right eye ball, occurring in the person of a female, aged seventy-six. The disease commenced by repeated attacks of inflammation of the organ, followed by loss of vision, enlargement of the eye-ball, and severe lancinating pain On admission into the Cumberland Infirmary the eye was somewhat increased in size, and the lower lid rendered prominent by a tumour which protruded between the lids, and prevented their closure. This tumour was firm and lobulated, about the size of three small peas, closely adherent to the sclerotic coat on the inner and lower part of the surface of the globe, and slightly overlapping the cornea; it was firm and unyielding in structure, painful on pressure, and apparently of a pale yellow colour upon its surface, which could, however, with difficulty be seen, owing to numerous small red vessels with which it was covered. The natural whiteness of the sclerotic was lost, and had become changed into a pale dusky leaden hue, with numerous large varicose vessels ramifying on its surface. On examination of the interior of the globe through the cornea, a minute portion of a discoloured greenish iris was visible on the upper and outer part, protruded forwards against the cornea, the remaining portion of the anterior chamber being occupied by a tumour, which appeared to have proceeded from the posterior part of the eye; this tumour, at its upper part, was of a dirty red colour, while the lower part, which covered nearly half the internal surface of the cornea, presented a black melanotic appearance. The globe was exquisitely sensitive; there was constant profuse lachrymation, and she said she was never free from a severe burning sensation. The history of the case, together with the symptoms, and appearance of the globe, led to the tolerably certain conclusion that the disease was of a malignant nature, amenable to but one mode of treatment, and that dangerous and uncertain—the extirpation of the globe. On the one hand there was her age, which rendered any operation hazardous, the possibility that some other part was similarly affected, and the probability, almost amounting to a certainty, that a like disease would sooner or later manifest itself either in the neighbouring structures or elsewhere. On the other hand there was the constant suffering which she endured, the apparent limitation of the disease to the eye itself, and the probability that if the operation were successful she would enjoy an interval of ease, even should the disease again appear, which it might fairly be hoped would not be the case, as at her advanced age it could not be expected that her life would be prolonged for any very lengthened period. Taking all these circumstances into account, it was resolved to propose to her the removal of the affected organ, she being at the same time fully apprized both of the immediate danger incurred, and the uncertainty of its being attended with a beneficial result. She at once unhesitatingly resolved to submit to the operation, which was accordingly performed five days after her admission. The patient being placed on a couch, the head supported by an assistant, an incision, about half an inch in length, was made from the outer canthus, in order to render the exposure of the globe more easy; the lids were then separated, and a sharp-pointed bistoury was passed deeply into the orbit, and carried completely round; the globe was next drawn gently forwards with a vulsellum, and the optic nerve and other structures which remained, divided by a pair of curved scissors, and the eye removed. Having waited for some little time, until the hemorrhage had ceased, the wound of the outer canthus was brought together by a suture, and the lids were carefully closed, a piece of lint being placed upon them, and retained in its position by a bandage. The patient, who bore the operation very well, had not a bad symptom afterwards, and was discharged in greatly improved health and spirits, rather more than a fortnight afterwards. It appears, however, that in the course of three or four months she was affected with dyspeptic symptoms, arising from derangement of the functions of the liver; that organ gradually increased in size, attended with much suffering, and she died eight months after the extirpation of the eye The body was not examined, but there can be no doubt but that the disease of the liver was of a malignant nature. An incision having been made into the tumour on the external surface of the eye, it was found to be of a hard cartilaginous structure, of a palish yellow colour, intersected with numerous dense white bands characteristic of scirrhus; its base was firmly adherent to the sclerotic coat, which was somewhat thickened. On a section of the eyeball being made, another tumour was found arising from the internal surface of the sclerotic at its posterior and inner portion, occupying the greater part of the posterior chamber; it had nearly destroyed all trace of the vitreous humour and lens, d in its progress forwards, all the other internal structures of the eye. The surface of this internal tumour presented shades of colour varying from a dusky red to black, in its interior the same colours were perceived, but instead of the black portions being blended with and lost in the surrounding redness, as on its surface, they were separated from t by well defined margins. It was composed in part of a reddish grey structure of a brain-like nsistence, and in part of a pultaceous matter of a much less firm character, of a dark brown colour, almost approaching to black, with which the fingers became stained during the examination.

[The following are the only articles of interest to he profession in the last number but one of the *Lancet*.]

Encephaloid Disease of the Pelvic Viscera.—Mr. Hardy narrates a case of encephaloid disease of the pelvic viscera occurring in a boy about five 'ears of age. The first symptoms resembled those of calculus in the bladder, and, on sounding, a calculus was apparently discovered in the urethra, which appeared afterwards to have descended into he membranous portion of that canal, after which, lthough no stone was voided, the symptoms of alculus entirely ceased. This was followed by pain nd hardness of the perineum, which gradually increased, and the swelling which formed became arger, and was attended by obstinate constipation. 'he case was then regarded as one of encephaloid isease. The tumour continued to increase in size, nd, after a time, very rapidly, a side view of the elvis showing that great deformity was resulting, s posterior aspect being projected very considerbly backwards, especially at the lower part, which ad also become elongated. In these two directions, he swelling continued steadily to advance till death, he enlargement and deformity of the last stages of he disease being truly hideous. Occasional febrile ttacks, accompanied by pain, referred always to he stomach and bowels, next ensued, and for many nonths before death, a red excrescence pushed itself it of the extremity of the rectum, and sometimes led a little. Emaciation also made great progress, nd the skin round the anus and perineum became iberculated, but did not ulcerate; the neighbouring integuments were traversed by numerous venous trunks. The child ultimately sunk. The examination of the body after death showed that emaciation was extreme; abdomen tumid; an immense tuberculated tumour, commencing at the scrotum anteriorly, passed backward to the anus, which it surrounded, and filled up the whole space situated between the tuberosities of the ischia, extending posteriorly, and also upwards to the base of the sacral bone. Its surface was very irregular, with a fungous excrescence shooting out of the right side of the anus. The skin covering the tumour was traversed by numerous vessels, especially over the lower extremity of the sacrum, and surrounding the anus The right groin was occupied by a hard tumour of uneven surface, of the size of a lemon; and a similar one, but much smaller, was found in the opposite groin. The whole hypogastric region was occupied by a solid tumour, the apex of which reached to the umbilicus. On dividing the large perineal tumour from the scrotum backwards to the rectum, its outer layer was found of the density and appearance of ordinary carcinomatous tumour, and creaked beneath the scalpel. As the incision was deepened, the scirrhous matter became mixed with softer material of the same general character, interspersed with numerous bloody points: and deeper still, it had the appearance and consistence of brain intermixed with coagula—the true fungoid tumour The whole of the rectum was affected by the disease, and was so compressed and straitened that the little finger could with difficulty be passed through its lower two-thirds. The mucous membrane was found intact. The excrescence before referred to, as pushing out of the bowel, was nothing more than an internal hemorrhoidal tumour. On opening the abdomen, the large tumour before spoken of was found to consist of the urinary bladder, the upper third of which appeared healthy, and the lower two-thirds invaded by the disease On opening this viscus, the diseased portion of the anterior wall was found full two inches in thickness; its posterior wall from five to six inches thick, in both cases white and of scirrhous hardness. The upper third of the bladder, though much thickened, was healthy in structure; it contained a few ounces of clear, straw-coloured urine, of the usual odour The cavity of the diseased portion was completely obliterated, or diminished, so as to form a small canal of the calibre of the urethra, with which it was continuous. The urethra itself was pushed considerably towards the left side of the pubic symphisis, but its mucous lining remained entire, as was also the case with the bladder. The disease completely enveloped the ossa pubis and lateral parts of the pelvic inlet, and extended upwards to the alæ of the ilia.

Femoral Aneurism Cured by Compression.—Mr. Mackern describes a case of aneurism of the femoral artery, which he treated successfully, by compression, using Signorini's tourniquet. The instrument at first was applied for half an hour at a time three times a-day, until, in the course of three weeks, it could be borne for six or eight hours, the seat of pressure being occasionally shifted along the course of the vessels. The treatment was continued for about five weeks altogether, and at the end of that time pulsation had entirely ceased, and there was a most sensible difference in the size of the tumour. The after treatment consisted in the application of an elastic bandage over the seat of the aneurism; a week after the cessation of the pulsation, the man returned to his employment, using the limb with caution, and has since remained free from any inconvenience, the tumour having nearly disappeared.

Imperforate Anus.—Dr. Smyth records a case of imperforate anus on which he had operated successfully. There was not any indication either by colour, or the touch of the situation of the rectum, or of any external perforation for an anus. He made an incision in the middle of the perineum, and the sphincter was observed to be straight, its mer sides being in close contact. This was cut through, and part of the levator ani and the fatty matter beneath were divided to the depth of an inch, no indications of the rectum being then discovered, the external wound was enlarged in both directions, the incisions being made cautiously upwards and ckwards; and still, when a depth of three inches had been obtained—Dr. Smyth being able to touch

the pubes in front and the sacrum behind, the wound being large enough to bury the index-finger — no appearance of the rectum could be made out However, when the child cried, a slight impetus was felt—a descending from behind—towards which, through the intervening substance, a trocar, as slender as an exploring-needle, was pushed, and on the second application the escape of gas through the canula showed that the bowel had been reached. An attempt was made to enlarge the opening with a director and bistoury, but failed; a full-sized trocar was, however, easily passed, and meconium discharged. On a subsequent occasion, Dr. Smyth passed a small pair of case-forceps along the canula, and taking hold of the bowel as near the opening as possible, he gently and gradually pulled it down upon the canula. This having been repeated two or three times, the opening in the bowel was brought down near to the external wound. The canula remained in for ten days. The sphincter now acts well, and a good anus is formed, if anything a little too far back; the bowels act naturally, a bougie being occasionally passed. A month has elapsed and no bad symptom has occurred. Dr. Smyth thus describes his motive for the final operative proceeding.—In making a canal through such a spongy substance as the cellular tissue, occupying the place where the bowel should be, such tissue will be found a most inadequate substitute for the muscular rectum; and in many cases the bowel may be found floating loose, or easily separated from its attachments, or these stretched, so that it may be brought down into its proper position; the passage then can easily be kept open, the tendency to healing, and so rendering another operation necessary, having in all cases been an immense obstacle to a perfect cure.

⁂ The case is far from being well told, and in some parts the statements are absurd, as, for instance—the greater part of the wound healed *by the first intention* around the canula *by granulations*. A perusal of any of the manuals on surgery will teach Dr. Smyth the difference between the healing of a wound by the first intention, and by granulations.

Tetanus.—Mr. Newton describes a case of tetanus occurring in an old sailor from a contused and suppurating wound of the great toe, in treating which he prescribed the tincture of aconite, with the tincture of tobacco, and solution of morphia, but without advantage. The man died the morning after the medicine was prescribed. None of the physiological effects of the aconite were produced.

Scotland.

Popliteal Aneurism.—Mr. Syme narrates, in the *Monthly Journal of Medical Science*, the case of a baker, thirty-two years of age, on whom he operated for an aneurism of the left popliteal artery, there being at the same time a commencing aneurism in the right ham. Considerable difficulty was experienced in passing a needle round the vessel, in consequence of its unusually firm adhesion to the sheath; and when the thread was tied, he felt the inner coats yield to a greater extent than upon any former occasion. Notwithstanding the evidence thus afforded of preternatural thickening, and morbid alteration in other respects, every thing went on well. The patient experienced no local uneasiness; the wound healed by the first intention so completely, that the lint applied to it never required to be changed; the tumour soon disappeared; the ligature separated on the twenty-first day, and the patient was dismissed cured of that aneurism; but was re-admitted five weeks afterwards to be operated on for the disease in the right ham. Mr. Syme then encountered still more difficulty in detaching the artery from its connections than on the previous occasion. At length the ligature was passed quite satisfactorily, and, not expecting any further trouble, he proceeded to tie it, but in so doing, he experienced a sensation as if the vessel had given away entirely, while a stream of arterial blood suddenly filled the wound, and confirmed the suspicion that it had done so. Pressure being made in the groin, he detached the artery higher up, and passed the aneurism-needle with the view of applying another ligature with less force. As the instrument, when withdrawn, was followed by an appearance of dark-coloured blood, causing a fear that the femoral vein might have been wounded, he determined not to tie the thread, and removed it, intending to rely upon pressure to control any hemorrhage that might ensue. None, however, recurred, and at the date of the report the patient was about to be discharged. Mr. Syme remarks that in the event of encountering a difficulty similar to that which was presented by this case, he should be prepared to meet it by the means of a small blunt hook, so fashioned as to embrace the artery, and hold it aside, while the edges of the aperture in the sheath being separated by catch-forceps inserted into them, the point of a narrow knife might sufficiently detach the firm connections of the vessel.

Urinary Calculus in the Female.—In the same journal, Mr. Syme records the case of an aged female, in whom there existed a calculus sacculated between the urethra and vagina. He dilated the orifice of the urethra by incision of the mucous membrane, and then divided the parietes of the canal, first forwards and then backwards, so as to lay it open through the whole extent from its orifice to the bladder, without at all injuring the vagina, and then extracted an oval calculus, measuring an inch and a quarter in length. The patient required to have her water drawn off for two days, after which she did not suffer any further inconvenience, and finally returned home.

Sinuses depending on Exfoliation of the Pelvis.—In the same journal, Mr. Syme draws attention to the fact, that sinuses in and about the pelvis, may be caused by exfoliation of portions of the ischium and pubes, induced either by muscular exertion, or external violence, and that the dead portion, being imprisoned by the dense structures surrounding it, may maintain a discharge of matter for an indefinite length of time. He then describes two cases of this disease, one resulting from muscular exertion, and the other from external violence. In the first case the sinuses were situated at the lower part of the belly, and upper part of the thigh, and the discharge was very profuse. It had continued for about fourteen months, and the patient was in a state of great exhaustion and emaciation. Finding that there was no difference, either real or apparent, in the length of the limbs, and that there was no sign of disease in the hip-joint or spine, Mr. Syme suspected that an exfoliation at the origin of the adductors or flexors of the thigh was the source of the discharge; and upon inserting a probe into the opening left by the abscess, distinctly felt a portion of dead bone. He dilated the sinus by incision upwards sufficiently to admit his finger, and then finding that the exfoliation lay in a cavity formed by very dense texture, partly by cutting with a blunt-pointed curved bistoury, partly by stretching with the finger, obtained sufficient space to extract two pieces of dead bone, one an inch, the other an inch and half in length, with about half these extents in breadth. They consisted of spongy or cancellated osseous texture; and one of them appeared to have formed part of the tuberosity of the ischium. He then carefully examined the cavity, and could not discover any more dead, or even denuded bone. The patient suffered little during the operation, and nothing after it. He noticed almost directly a diminution of the discharge, which in the course of a few days became so scanty as to occasion no inconvenience. His strength daily increased, and he was, at the date of the report, not quite four weeks from the operation, about to be discharged. The second case was more complicated. The patient, a lad eighteen years of age, was admitted with a very tight stricture at the bulb, caused about eight months previously by the fall of a very heavy piece of iron machinery on the pelvis. Extravasation of urine and extensive sloughing of the perineum followed, with the separation of a piece of bone at the end of a month. The sore then gradually healed, but with increasing difficulty of micturition, which at length nearly ceased through the proper outlet, and was effected chiefly by an orifice in the perineum. This opening was situated on the right side, near the hip, in the centre of a large and very firm cicatrix, resulting from the loss of substance that had taken place in the first instance. After Mr. Syme had succeeded in dilating the urethra to a certain extent, he carried a moderate sized bougie on to the bladder, and in so doing, he encountered a hard substance, not giving the clear ring of stony matter, and which, therefore, he concluded to be a piece of bone. Having passed a small grooved staff into the bladder, Mr. Syme made a free incision on the left side of the perineum, the sinus that opened on the right side being so long and tortuous, that a probe could not be conveyed through it to the object for removal. Having inserted his finger through the dense and thickened textures, he felt a piece of bone lying in a cavity of cartilaginous firmness, and after dilating the aperture sufficiently, he extracted two exfoliations, which together measured two inches in length, and one in breadth. They seemed to have formed part of the symphysis pubis. After the operation, the patient confessed that he had suffered the greatest distress in attempting to make water, but had concealed it, for fear of what might be considered necessary to afford him relief. He felt perfectly easy after the exfoliations were removed, and was dismissed about a month after the operation.

ORIGINAL LECTURES.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

By G. J. GUTHRIE, F.R.S., &c.

Lecture III (continued).

Baron Dupuytren on aneurisms complicating fractures, and wounds by fire-arms, and their treatment by Anel's operation; M. Delpech's case; Baron Dupuytren's case of false aneurism from pistol-shot wound of the leg, with successful ligature of the femoral artery; Remarks on his practice; Case of diffused aneurism of the thigh, following fracture of the femur, terminating by fatal mortification; Case of true popliteal aneurism, becoming diffused by rupture of the sac; incision into the false aneurism, amputation, and death; Sir Astley Cooper's case of ligature of the femoral, from wound in the leg, secondary hemorrhage, and amputation; Mr. S. Cooper's successful case of ligature of the femoral, for wound of the leg; Mr. S. Cooper's successful case of ligatur of the popliteal artery, for a wound in the calf of the leg; Mr. Guthrie's successful case of ligature of the perineal artery at the seat of injury, Mr. Hall's successful case of ligature of the posterior tibial artery at the seat of injury; Mr. Arnott's successful case of ligature of the posterior tibial artery at the seat of injury, Mr. Roche's case of ligature of the posterior tibial artery for aneurism after amputation; Mr. Collier's case of ligature of the posterior tibial for secondary hemorrhage after hospital gangrene; Mr. Stanley's cases; The operations for placing a ligature on the posterior tibial artery; All such wounds, and all recent aneurismal swellings resulting from them, are to be treated by incision, and the application of two ligatures to the artery.

The Baron Dupuytren in 1828 published a paper entitled "Memoire sur les Aneurismes qui compliquent les fractures et les plaies d'armes à feu et sur leur traitement par la ligature pratiquée suivant la methode d'Anel," in the *Repertoire General d'Anatomie et de Physiologie*, which operation he recommends as superseding that of amputation, which, up to that time, he says, had been usually performed in France in such cases, and with the view of avoiding the operation I had recommended some years before on the part injured, by cutting through a mass of muscular fibres. The operation the baron did was that of Hunter, and not, as he states, that recommended by Anel, who never performed one on that principle. A strange error for the baron to have fallen into, but no less so than the statement made at page 22 that he had consulted in vain both ancient and modern authors on this subject, although Breschet had translated Mr. Hodgson's work on the Diseases of Arteries nine years before, in which my earliest cases were especially noticed. His memoir shows, at all events, that the practice the Baron Dupuytren recommended to the surgeons of France in 1828 as worthy of their adoption, had been tried

by many of the surgeons of the British army in 181 and 1812, and found wanting, and is an honourabl testimony to their labours. The baron supports his views by the relation of seven cases, which I have transcribed in my work on this subject, althougl two only bear effectually upon it. One is by Delpech the other by himself. In Delpech's case (No. 11 the patient, Jacques Boudet, thirty years of age had his left leg broken (a comminuted fracture) or the 8th of May, 1815, by the wheel of a car laden with hay. On his arrival at the Hospital St. Eloi, M. Delpech found the limb enormously swollen, and this swelling was accompanied by pulsations, which were very distinct near the calf, and more or less perceptible when pressure was made on or removed from the above artery. The femoral artery was tied next day, and the patient recovered, and was discharged cured on the eighty-second day.

In this case it was not known whether the anterior or the posterior tibial artery was wounded, or the femoral, or all three, or the popliteal alone. An incision made, even in the right place, must have made a comminuted fracture a compound one, and greatly endangered the life of the patient. The operation was therefore a fair experiment, and if it failed, amputation was still a resource before mortification had taken place. It is not exactly a case in point.

The baron's seventh case, that of Captain de Gambaud, fairly however meets every point, and as far as it goes fully establishes his opinion.

Case 42.—"M. de Gambaud received, February 10th, 1818, a wound from a horse pistol, which entered the upper part of the right leg, from the front backwards, and from the outside inwards, passing between the tibia and the fibula, which latter it slightly injured. A violent bleeding immediately ensued A young surgeon stopped the hemorrhage by the application of a compress and bandage. The leg became swollen and very painful, to which succeeded an alarming numbness; nevertheless life remained in the limb, and no outward bleeding occurred till the thirteenth day; but during this time an internal effusion had taken place, and an aneurism was developed, which increased every day, and became more observable from its synchronous movements of expansion and contraction with those of the pulse.

"The bleeding was renewed several times in a few days, and greatly weakened the patient, in spite of the assistance, both internal and external, which was afforded him. The foot and leg were of a violet colour, swollen, cold, and numb On the upper part of the leg there was a swelling accompanied by tension, and a movement of expansion and contraction, synchronous with the action of the heart. There were two small round openings with unequal edges on this tumour, situated the one at the back of the leg near the fibula, the other on the inner edge of the calf The first was where the ball entered, and the second where it came out They both for a few hours had been closed by clots of blood, that each pulsation threatened to raise and force out. A tourniquet applied to the lower part of the thigh on the course of the femoral artery, would of course lessen the impulse of the blood, but could not prevent its getting to the tumour, and giving rise to frightful shocks.

"Such was M. de Gambaud's state; the wound that he had received, the first hemorrhage that he had sustained, the tumour which had been formed from the first moment that the blood had ceased to flow outwardly, the volume and tension of this tumour, the nature, extent, and strength of its movements, the repeated bleedings that the patient had suffered, all proved that the ball had destroyed one or several of the great arterial trunks in the ham.

"What was to be done? We could not again make use of compression, which had already been fairly tried, and had not prevented five or six hemorrhages taking place, which had reduced the patient to an alarming state of weakness. Ought we to place a ligature on the extremities of the divided vessels?

"But what were those vessels? Was it the anterior or posterior tibial artery, or the peroneal, or the popliteal artery, or was it several of these at the same time? If it were one or more, how should we attack them, before or behind, or on these two points successively?

"But to all who know the depth at which these vessels are situated, their relation to the bones, muscles, and nerves, this project appears impracticable. Could we even determine exactly, which was impossible, which vessel was injured, how could we get at it? How could we distinguish it from the soft, torn, and bruised parts which would surround it? or how would the instruments and the threads necessary to tie a ligature be got to the bottom of wound thus deep, and between the bones? The amputation of the thigh seemed the most promp and safe remedy; and this was what my youn colleagues wished, and only waited for my sanctio to perform. Amputation is not, however, withou danger, and in my opinion will kill three out o twelve, when practised even upon young and health persons, such as are chosen for its victims on th field of battle. I did not therefore recommend tha it should be had recourse to, but advised the placing of a ligature on the femoral artery. If the even did not turn out as I expected, if the blood brough back by the collateral arteries continued to flow either at the superior or inferior extremity of the divided artery, or if from any other cause the ligature should prove insufficient, it would become the first part of an amputation, neither more dangerous nor more painful from being performed a two intervals. The operation was performed in one minute. It proved successful, and M. de Gambaud was quite cured in three months."

To support his opinion that this case should lead he way towards erecting the practice pursued into a precept in surgery, he is forced to consider certai points as facts, which have never been demonstrated o be facts; but I shall give his own words:—

"The ligature, in suspending the course of the blood in a divided vessel, the solution of continuity of which has caused an external and internal bleeding, gave time and means to the inflammation to cicatrise the wounds in the vessel, and to render he cut extremities impermeable to the blood which he anastomosing branches might bring to them.

"To judge by analogy, this obliteration ought to be more easy and more certain after a gunshot wound than any other.

"One of their most remarkable effects is to contract (*froncer*) the orifices of the vessels, to concrete or coagulate the blood contained in their extremities, and to render them impervious."

Remarks.—This last passage cannot be admitted as a correct statement of the effects of a gunshot wound on arteries

I have shown in the preceding observations the real effect of a ball on the extremity of a divided artery, and that the appearances depend very much on the size and structure of the vessel. In what manner the ball can contract (*froncer*) the orifice of an artery has never been shown, neither can it be easily understood, inasmuch as the act of contracting must be a vital act dependant on the powers of the artery itself. If it be a mechanical act, arising from injury, it must be a contusion; and this cannot be advanced as a process likely to consolidate the end of the vessel, it being now well known that the first and most simple state of adhesive inflammation is the best calculated for permanent closure of a divided artery.

When a wounded artery has been tied at a distance from the wound, as in the case of M. Dupuytren, it is certainly true that if the blood can be prevented by this means from passing into the divided vessel, there will be a greater chance of the natural processes of inflammation and granulation which are taking place in and around it, closing it up, than if the blood be allowed to flow through it. But it is only then a chance. It is impossible to calculate the time which nature may require to bring the blood by the collateral vessels into either the upper or the lower end of the vessel; it may occur immediately; it may not do so for hours or for days, and on the speculation that it may not do so, the first hope of safety depends—the second on the further accidental circumstance that the end of the artery may be closed in the interval. Surely this cannot be considered a scientific operation, and fit to be erected into a precept in surgery, which depends on two accidental circumstances, neither of which can in the slightest degree be calculated upon.

There are many other reasons why the operation was a bad one in this case, and always will be a bad one in all similar cases. The patient was made to undergo the chance of mortification of the extremity, which it is probable would have taken place, if the operation had not been delayed until thirteen days after the first hemorrhage occurred from the wound, during which time the inflammation in the limb had given the collateral vessels a disposition to enlarge. The wound itself was not treated as the principles of surgery require. A quantity of decomposed blood was pent up under and between the muscles of the calf of the leg, together with some of the patient's clothes, and some spiculæ of bone. In a case like this, unattended by the fear of hemorrhage, the baron should have enlarged the wound, cleared away the clots of blood, and have placed it in a simple state. There cannot be a doubt on the subject, and the operation of making an incision through the muscles of the calf of the leg would have enabled him to do all this, and to have secured the vessels, if there had been even four bleeding extremities, without any difficulty or danger.

The Baron Dupuytren applied Mr. Hunter's theory of the operation for aneurism to the treatment of a wounded artery, and succeeded by chance. Others have done the same long before him; but nothing which is dependent on chance or accident can ever become a principle in surgery, and I understand the baron became so thoroughly convinced of this before his death, that he at last advocated the principle that a wounded artery should be tied at the injured part, and not at a distance.

Case 13.—A gentleman was thrown from the top of a coach at Chatham, and suffered a severe injury of the thigh, which broke the bone. No further injury was suspected, although the lower and internal part of the thigh swelled very much, until the toes began to turn black and to mortify. My opinion was now desired, and my reply was, amputate the limb, or you will lose your patient by the extension of the mortification, which eventually occurred.

Remarks.—If the mortification had not taken place, the surgeon could with propriety have awaited the progress of the diffused aneurism, there being no external wound. If it continued, nd remained stationary, or only slowly increased during weeks, the operation for its cure by ligature of the artery above would have been a fair experiment. If, on the contrary, the aneurismal swelling increased rapidly, or the consolidation of the fracture did not take place, amputation was the only resource.

Case 14.—A man was admitted into the Westminster Hospital, under the care of Sir Anthony Carlisle, having had a beating tumour in his ham, which had suddenly disappeared on something apparently giving way in his leg, which caused it to swell to nearly double the size of the other, from immediately below the knee to the ankle. There was no doubt in my mind of its being a diffused aneurismal swelling from rupture of an aneurismal sac, and I suggested the propriety of placing a ligature on the femoral artery, as for an ordinary aneurism, and awaiting events; such as laying open the soft parts of the leg for the evacuation of the coagulated blood, or of the matter which might form, or to make the ligature of the artery the point of amputation, if gangrene should supervene. Sir Anthony Carlisle preferred laying open the leg at once; this he did by an incision through the calf of the leg, opening into a largely dilated and ruptured sac, formed at the origin of the posterior tibial artery. The coagula being removed, the popliteal artery bled vigorously; the anterior tibial opening into the sac did the same, and the lower end of the posterior tibial poured out arterial blood even more vigorously than the anterior tibial. Sir Anthony Carlisle decided on amputating the limb, which he did, and the patient died.

Remarks.—If this diffused aneurismal swelling had followed a wound inflicted some two or three weeks before, the three bleeding arteries and the effused blood would not have rendered amputation admissible unless mortification supervened. It the previously diseased state of the artery which had led to the formation of the aneurism that induced me to recommend that it should be tied in the thigh as an experiment, and after the diseased

artery with its sac, &c., had been laid open, that the limb should be amputated.

CASE 45.—Sir Astley Cooper at one time shared in the same opinion as Dupuytren, and tied the femoral artery for a wound in the leg below the knee. Mr. Green, who was present, informs me that the bleeding returned, the limb was amputated, and Sir Astley abandoned both the theory and the practice.

CASE 46.—Mr. S. Cooper did the same thing at Brussels after the battle of Waterloo, and succeeded; but he admits in his dictionary, article "Arteries," that he succeeded only because the collateral branches did not re-establish the circulation in the lower end of the artery, or that it had been closed in time to prevent it when they had done so. This was an operation successful by chance, and not on principle. Mr. S. Cooper did better in 1834, in the following —.

CASE 47.—The man had a wound in the calf of the leg, and the house-surgeon of University College Hospital having failed after several trials to secure effectually the wounded artery, he (Mr. Cooper) tied the popliteal, and succeeded. In this case he descended from Hunter to Anel, but this also only succeeded by accident, and another operation would have been required if the collateral circulation had been early restored, whereas a single straight incision through the muscles of the calf would have enabled him to tie all the cut vessels, even including the popliteal, or principal trunk. I am quite satisfied that if another case of the kind should occur to the learned professor of surgery, he would tie the artery above and below the part injured, and by the operation I shall show you has succeeded so well.

CASE 48, by Mr. Stanley.—A butcher in slaying an ox received a wound on the inner side of, and about two-thirds down the leg; the length of the wound was not more than half an inch, but it penetrated from the inner almost to the outer side of the leg, and deeply in the direction of the posterior tibial and peroneal arteries. Profuse arterial bleeding immediately ensued. A bandage was placed around the leg, which was not disturbed for eight days; then, on removing it, the hemorrhage returned. He freely enlarged the wound, and exposed the posterior tibial artery, which was of unusually small size, and was partially divided. He placed two ligatures around the artery, one above and the other below the wound in it.

Much constitutional derangement followed, with inflammation of the absorbents up the thigh. This was succeeded by an attack of delirium tremens, from which the man sunk on the fifteenth day from the receipt of the wound; but there was no return of bleeding after the ligature of the posterior tibial artery.

On examining the limb, the posterior tibial artery throughout was found to be not more than half its usual size. The peroneal artery in its whole length was more than twice the size of the posterior tibial. It was found that the knife in its passage through the leg, having partially divided the small posterior tibial artery, had also penetrated the large perineal artery at a point where it was very deeply situated, in a hollow between the fibula and the inter-osseous ligament, but which had not bled.

CASE 49, by Mr Stanley.—A boy, ten years of age, in walking, slipped his foot through a pane of glass, which wounded the inner side of the leg in the hollow between the inner malleolus and os calcis. Profuse bleeding immediately ensued, which was stopped by a bandage. Three days afterwards the removal of the bandage was followed by a flow of arterial blood. He enlarged the wound, exposed the posterior tibial artery, and observed a hole in the side of it, from which the blood issued. He placed two ligatures around the artery, about an inch distant from each other, the one clearly above, the other below the orifice in the vessel. About an hour afterwards the arterial bleeding returned, and on sponging out the wound, to his surprise, he found that the blood escaped from the hole in the side of the artery. He then placed two additional ligatures around the artery close to the hole in it. There was no return of the hemorrhage.

It was presumed that a branch had conveyed the blood into the artery in the interspace of the two ... which were first applied.

The following case was published by me in the 7th vol. of the "Transactions of the Medico-Chirurgical Society."—

CASE 50. Henry Vigarelic, a private in the German legion, was wounded on the 18th of June, at the battle of Waterloo, by a musket ball, which entered the right leg immediately behind and below the inner head of the tibia, inclining downwards, and under or before a part of the soleus and gastrocnemius muscles, and coming out through them, four inches and three quarters below the head of the fibula, nearly in the middle, but towards the side of the calf of the leg. In this course it is evident that the ball must have passed close to the posterior tibial and peroneal arteries; but as little inflammation followed, and no immediate hemorrhage, he was considered to be one of the slighter cases. On the latter days of June he occasionally lost a little blood from the wound, and on the 1st of July a considerable hemorrhage took place, which was suppressed by the tourniquet, and did not immediately recur on its removal. It bled however at intervals during the night; and on the morning of the 2nd it became necessary to re-apply the tourniquet, and to adopt some means for his permanent relief.

The man had lost a large quantity of blood from the whole of the bleedings, his pulse was 110, the skin hot, tongue furred, with great anxiety of countenance: the limb, from the application of the tourniquet from time to time, was swelled, a quantity of coagulated blood had forced itself under the soleus in the course of the muscles increasing the size of the leg, and florid blood issue from both openings on taking the compression o the femoral artery. On passing the finger into th outer opening, and pressing it against the fibula, sort of aneurismal tumour could be felt under it, and the hemorrhage ceased, indicating that the peroneal artery was in all probability the only vessel wounded.

In this case there was, in addition to the wound of the artery, a quantity of blood between the muscles, which in gun-shot wounds accompanied by inflammation is always a dangerous occurrence, as it terminates in profuse suppuration of the containing parts, and frequently in gangrene. Its evacuation therefore became an important consideration, even if the hemorrhage had ceased spontaneously.

The man being laid on his face, with the calf of the leg uppermost, I made an incision about seven inches in length in the axis of the limb, taking the shot hole nearly as a central point, and carried it by successive strokes through the gastrocnemius and soleus muscles towards the peroneal artery, which I attempted to discover, but this was more difficult than might be supposed, after such an opening had been made. The parts were not easily separated, from the inflammation that had taken place, and those in the immediate track of the ball were in the different stages from sphacelus to a state of health, as the ball in its course had produced its effect upon them, or their powers of life were equal or unequal to the injury sustained.

The sloughing matter mixed with coagulated blood readily yielded to the back of the knife, but was not easily dissected out. The spot which the arterial blood came from was distinguished through it, but the artery could not be perceived, the swelling and the depth of the wound rendering any operation on it difficult. To obviate this inconvenience, I made a transverse incision outwards, from the shot hole to the edge of the fibula, which enabled me to turn back two little flaps, and gave greater facility in the use of my instruments. I could now pass a tenaculum under the spot whence the blood came, which I raised a little with it, but could not distinctly see the wounded artery in the altered state of parts, so as to secure it separately. I therefore passed a small needle, bearing two threads, a sufficient distance above the tenaculum to induce me to believe it was in sound parts, but including very little in the ligature, when the hemorrhage ceased; another was passed in the same manner below, and the tenaculum withdrawn. The coagula under the muscles were removed, the cavity washed out by a stream of warm water injected through the external opening, the wound gently drawn together by two or three straps of adhesive plaster, and the limb enveloped in cloths constantly wetted with cold water. The patient was placed on milk diet.

On the 4th, two days after the operation, the wound was dressed and looked very well; the weather being very hot, two straps of plaster only were applied to prevent the parts separating. On the 5th, a poultice was laid over the dressings, in lieu of the cold water, the stiffness becoming disagreeable. On the 6th, as the wound, although open in all its extent, did not appear likely to separate more, the plasters were omitted, and a poultice alone applied. On the 8th and 9th it suppurated kindly; and on the 10th, or eight days from the operation, the ligatures came away, the limb being free from tension, and the patient in an amended state of health, his medical treatment having been steadily attended to.

From this period the cure went on, although slowly, without accident; a small abscess formed at the inner and lower edge of the soleus muscle, but closed shortly after its contents were evacuated. The wound was entirely healed in three months, but the leg was bent on the thigh, and required mechanical means for its extension.

The length of the fibula is sixteen inches. The cicatrix of the wound made by the ball is four inches and three quarters below the head of the fibula. The sound limb, four inches and three quarters from the head of the fibula, is thirteen inches and three quarters in circumference. The limb operated on eleven inches and three quarters, being a diminution of two inches. The length of the cicatrix is six inches and a half. The peroneal artery was tied therefore by computation one inch and a quarter below where it is usually given off by the posterior tibial.

The man was brought to England to the York Hospital at Chelsea, and walked about without appearing lame, although he could not do so for any great distance. He suffered no pain, except an occasional cramp in the ball of the foot, and some contraction of the toes, which took place generally when he rose in a morning, and continued for a minute or two, until he put them straight with his hand; this I did not attribute to the operation, but to some additional injury done to the nerves by the ball in its course through the leg.

Mr. Hall, of East Retford, has published the following case in the *London Medical Gazette*, of the 6th February, 1846:—

CASE 51.—April 16, 1841. A gentleman, upwards of sixty, had been thrown from his horse, and was reported to be bleeding to death from a wound of the leg. In less than half an hour after the infliction of the injury, his clothes were saturated with blood, and a considerable quantity had flowed into his shoe. He was cold and faint, with a feeble pulse. A little brandy and water were immediately given to him, and he was placed in bed. On removing his clothes, a wound of about an inch in length was seen in the calf, a little below the junction of the upper with the middle third, and from which the blood was now again beginning to flow freely. A tourniquet was applied over the femoral artery, which retarded the hemorrhage, but did not altogether check it. The nature of the injury was at once evident, and the necessary steps immediately taken for securing the posterior tibial artery. Introducing a long narrow bladed knife into the wound, the muscles were carefully divided above and below the seat of injury, down to the deep fascia, which was now clearly seen on sponging away the coagulated blood, and into which a small opening had been made. The manner in which the injury had been sustained was doubtful. When it occurred, the old gentleman was riding a horse that plunged violently, and threw him with great force to the ground; his foot was fixed in the stirrups, and he was dragged some distance; he says, when his foot got at liberty, the horse kicked him with considerable violence on the leg; he had neither trousers nor gaiters upon his leg, which was only protected by a thick stocking. On looking at the shoes of the horse, it was found he had been shod behind with what are called "caulkings," one of which it is supposed had been driven into his leg. The opening in the fascia was enlarged, and, after removing a good deal of coagulated blood, the artery was found, and secured by passing a ligature above and below the wound, the vessel was

divided between them. The wound in the muscles was then brought together, and a bandage applied from the toes to the upper part of the thigh; the patient appeared to experience much relief from this, which in a great measure checked the spasm and quivering of the muscles, which was somewhat severe during and immediately after the operation. A large dose of liq. opii. sed. was given. No constitutional disturbance worthy of notice took place. Both ligatures came away on the 12th day after the operation. Mr. Hall saw this gentleman some time afterwards; he was on horseback, and told him he could not discover that the leg on which the injury was sustained was worse than the other; and that it did its work very well.

CASE 52.—A robust young man was admitted into the Middlesex Hospital on January 1, 1815, with a punctured wound from a joiner's chisel in the calf, at the junction of the upper with the middle third of the leg, and a little to the inner side of the mesial line. Arterial and venous blood flowed in quantity. From the situation, depth, and direction of the wound, as ascertained by a probe, it was evident that the posterior tibial was probably wounded. Mr. Arnott determined to cut down upon it at once, in order to secure both ends. For this purpose, taking the punctured wound as a centre, he made an incision through the skin and muscles of the calf, to the extent of six and a half inches; the deep fascia being thereby exposed, the opening in it made by the chisel was enlarged to the extent of two inches. After considerable difficulty from the bleeding, it was ascertained, that besides the wound in the posterior tibial, both venæ comites were divided. On account of the troublesome character of the bleeding from these veins, and the difficulty created in discovering the artery, one of the veins had a ligature placed on both ends, whilst the lower end of the other was subjected to pressure. Two ligatures were then placed on the artery, one above the other below the puncture, it was not till the latter was tied that the hemorrhage ceased. Little febrile disturbance followed the operation; the lower ligature on the artery came away on the eighth day, the upper on the ninth. During the night of the eleventh, some bleeding took place from the lower angle of the wound, which was not arrested by compression of the femoral artery, but which was easily checked by displacing some coagula from the wound, and making pressure at the lower part of it by means of a small compress of lint, which was left in the wound. This was removed in three days, and the case proceeded subsequently uninterruptedly to a favourable termination. The wound cicatrised in less than two months, and the patient recovered with a perfectly efficient limb.

CASE 53.—John Sullivan, 27th regiment, had his leg amputated six inches below the knee, at Tarragona, in April, 1833, by Staff-surgeon Roche, in consequence of a compound fracture and dislocation of the ankle-joint. Three days afterwards hemorrhage took place, and a small aneurismal tumour about the size of a pigeon's egg was discovered bleeding about an inch above where the ligature had been applied. This part of the calf was laid open, and a ligature applied midway between the sac and the origin of the artery from the popliteal. It succeeded, and was the operation of Anel, justly preferred to that of Hunter, because there was an open stump with which the little aneurism was continuous.

CASE 54.—Jean Debret, a French prisoner of war, came under the care of Staff-surgeon Collier, in the beginning of September, having been wounded at the battle of Waterloo by a musket ball, which broke both bones of the left leg, and requiring several incisions to be made into the soft parts, which were greatly implicated by disease. He had suffered an attack of erysipelas, and the constitution had sympathised greatly with the injury, and was little able to resist it. Towards the end of the month the wound assumed the character of the hospital sore or gangrene, which spread rapidly over all the parts down to the tibia. The extensor tendons were dissected bare for the space of four inches, and the interosseous membrane even appeared to have partaken of the disease. On the 4th of October hemorrhage took place about two inches and a half above the ankle-joint, which was arrested by pressure. On removing this and some coagula which covered the artery, it bled furiously; a little dissection laid the artery bare an inch and a half above this spot, where a ligature was passed around it, and the bleeding never returned. The ligature came away on the sixth day, and the man recovered and was sent to France with a serviceable leg although lame.

Several of our best anatomists, in order to avoid the operation I have recommended, which Messrs. Hall and Arnott have so well performed, and which renders the division of the great muscles in the calf of the leg necessary, advise a tedious and more difficult operation to secure either the posterior tibial or the peroneal artery; and as a mistake may be made as to which is divided, when the wounding instrument has passed from side to side, and blood flows freely from both orifices, they further advise that one should be tied first, and if not successful, that a second operation should be done to expose the other, instead of doing my operation at once, and thereby enabling the operator to place a ligature on either, or on both.

The operation of tying the posterior tibial artery in the middle of the leg, after the ordinary methods recommended, is not very easily accomplished. It is said the leg should be bent, the foot extended, and both placed on the outer side; an incision should then be made, about four inches in length, along the inner edge of the tibia, through the integuments and fascia (the internal saphena vein should be avoided), the edge of the gastrocnemius muscle will be exposed, this may be easily raised and drawn to the outer side; a director should then be insinuated beneath the head of the soleus, on which this muscle must be divided from its attachment to the tibia; the deep fascia of the leg will then be seen very tense and strong, binding down the deep-seated muscles and the tibial nerve and vessels; this must be cautiously divided on the director passed beneath it. The foot should now be extended as much as possible, and the knee placed in the flexed position, to relax the superficial muscles on the back part of the leg, when the artery may be felt pulsating about an inch from the edge of the tibia; the veins are then to be separated from the artery with a blunt instrument, and the aneurism needle passed round the latter in a direction from without inwards, so as to avoid the posterior tibial nerve.

On the dead subject this operation is not attended with much difficulty; in the living however the case is very different: the muscles are then rigid and unyielding, and when the fascia which covers them is divided, they leave their natural situation and become much elevated, so as to make the situation of the artery appear as a deep cavity, at the bottom of which the vessel is placed. Add to this that the artery is cut across, has retracted upwards and downwards, that both ends may not bleed and cannot be found in the small space which has been made, although both require to be tied; add to this that the surgeon may have made a mistake, and finds that it was the other and more distant artery that is wounded, or that both are injured, and the operator will be in a very unenviable condition.

Let us proceed however with the simple case. The operator has cut his four inches, has turned up the edge of the gastrocnemius, and has insinuated his director under the head of the soleus, which he has also sliced away from the bone. The artery is still an inch inwards, bound down by a strong fascia; pulsating it is said, bleeding I say if it pulsates, all this time as fast as it can, or else a tourniquet has been applied, and the pulsation has been suspended. The fascia must be cut immediately over or by the side of the artery; it will not do to separate it from the bone and then push it over; it cannot be done, and would not do if it could. The artery must then be allowed to bleed. The tourniquet must be unscrewed, and the wound is immediately filled with blood. Nothing can be done until this is sponged out, and to enable this to be done, the tourniquet must be screwed up, and then the surgeon is pretty much where he was before. We will suppose that he has succeeded in dividing the fascia, for an inch at least in extent, over the artery, without injuring it or anything else. What is directed to be done next? Why certain evolutions are to be performed with the leg, as described above, and then the surgeon is to separate the two veins from the artery with a blunt instrument, and then he is to pass an aneurismal needle under the artery from without inwards, so as to avoid the nerve. Now all this is to be done in a hole, the bottom of which the operator can scarcely see, and if he could it would not signify, because it is on the side of the bottom of the hole he is to perform these different evolutions on parts too likely to be covered continually with blood; for although the bleeding from the upper end of the artery may be suppressed by the tourniquet, that from the lower end in young persons may not; and at all events the unscrewing of the tourniquet will cause a most troublesome oozing, occupy a great deal of time, and give rise to much pain. Lastly, when the operator comes to the fascia, he will find his first four inches will not give him room enough; if he succeeds in dividing it, and tries to find the artery, the deficiency of space will cause him to enlarge his first incision; and before he has completed his operation, the quantity of cutting, retracting, pulling, sponging, and bleeding will make it to himself a most unsatisfactory operation. Of the patient's sufferings we will say nothing. If a bystander should inquire, why this most painful, difficult, bloody, tedious, and dangerous operation (dangerous from the chance of failure) is done?—the answer would be, solely because it is not usual to make a longitudinal incision in the muscles of the calf of the leg; an incision which if made by accident would be pronounced to be one attended with little danger, and not likely to lead to any subsequent detriment. Let us compare this operose proceeding with the following simple operation:—

An incision is to be made six or seven inches in length, by successive and rapid incisions, through the integuments and muscles of the calf of the leg down to the fascia. The centre of the incision is to be on a line with the holes made by the wounding instruments, or if they are diagonal to each other between them; and it may be either directly in the middle of the calf, or a little to the side of, or directly over the artery supposed to be wounded: it is not material which. The smoothness of the fascia points it out, and the loose cellular membrane connecting the divided muscles to it, allows of the edges of the long incision being easily separated, and to such a distance as to admit of the exposure of the posterior tibial artery, its two veins, and the nerve, in as distinct a manner as any other arteries, veins, and nerves, can be exposed in the human body. The tourniquet is now to be unscrewed, and the bleeding, if the wound did not bleed before, leads to the spot where the artery is injured. The artery may be laid bare in its whole extent by as common a piece of dissection as any ever practised, and nothing can interrupt the application of the ligature. The nerve, the veins, and the fascia cease to be surgical bugbears, and the operation is as simple as any in surgery. No surgeon or anatomist can dispute this statement. Mr. Stanley, Mr. Hamilton, M. Berard, and others, have successfully treated wounds in the lower part of the posterior tibial artery in this way, and a careful consideration of the cases related, and the facts and arguments advanced, must, I am satisfied, cause every surgeon to conclude that there is only one right way of treating wounded arteries in the leg.

My kind friend, Mr. Carmichael, of Dublin, at the conclusion of his case 39, reproaches me with having said, "In all cases of aneurism of the gluteal and sciatic arteries, the internal iliac should be tied, instead of an operation on the part itself." He admits he is aware that I do not mean this sentence to apply to aneurismal tumours, the consequence of wounds, but only to aneurisms formed by after injury of the artery. It was however, he says, quoted against him as an authority in his case which I have transcribed, and he is therefore desirous that all ambiguity on this point should be removed, that I should on all future occasions explicitly declare that all wounded arteries, and all aneurismal swellings of recent date occurring after wounds of arteries, are to be treated by ligatures of the artery at the wounded part. He desires that I should do this in such manner as to remove all doubt on the subject. I now comply with this desire in the plainest possible manner, and declare that any other mode of proceeding is contrary to those principles which ought to guide the surgeon not only in all such cases, but in all others in which it can by any possibility be applied.

A Course of Lectures on Hernia,

By JOHN FLINT SOUTH, Esq.,
Surgeon to St. Thomas' Hospital, and Professor of Surgery to the Royal College of Surgeons.

(Delivered in the Theatre of the College, and revised by the Professor for the MEDICAL TIMES.)

LECTURE III.

Experiments of M. Jules Cloquet, on "reduction en masse;" his explanation; Mr. Luke's statement; Dupuytren's opinion; Treatment; Can "reduction en masse" be remedied? Opinions of Dupuytren and Cloquet; Professor South's advice under such circumstances; Necessity of immediate recourse to the operation, when attempts at reduction have failed; Other proposed remedies; Purgatives, clysters; Opinions of Pott and Monro primus; Tobacco in clysters, urged by Sir Astley Cooper; Professor South's opinion; Tartar emetic condemned; Treatment when the patient refuses the operation; Practice of Monro Primus; Petit's case; Action of cold; Cline and Sharp's case; Treatment after the reduction.

This subject had not specially attracted the attention of English surgeons, except when during the operation for strangulated rupture, the unopened sac presumed to have been the bowel had been under that mistake, returned, with its contents still retained, into the belly, and thrust between the peritoneum and transverse or iliac fascia. This, though actually the same accident, differs from reduction in mass, inasmuch as the parts in front of the neck of the sac are divided by the knife, under the supposition of dividing the stricture, and the finger being introduced makes a cavity into which the rupture-sac, separated from its connexions by the operator's fingers, is either turned up on itself, or pushed. But beyond this reduction in mass had not been noticed, previously to Mr. Luke's excellent paper upon the subject was read in 1843 before the Royal Medical and Chirurgical Society, where, from the published report of the proceedings of the meeting, it appears to have been considered novel.

The possibility of effecting a reduction in mass by violent employment of the taxis had been doubted or denied, till experiments with this object had been made on the ruptures of dead persons by M. Jules Cloquet, who "accomplished reduction in mass in about twenty-five instances, partly of ruptures, either strangulated or otherwise irreducible, partly of empty hernial sacs. This was effected most easily in direct inguinal, next in femoral, and lastly in oblique inguinal ruptures. But he never succeeded with umbilical ruptures in adults."

M. Cloquet gives the following very clear and satisfactory account of the way in which this unhappy reduction is effected:—"When the neck of the sac does not adhere very strongly to the aponeurotic opening, and the latter is also somewhat dilated, which is not uncommon, in violently pushing the rupture towards the cavity of the belly, the adhesions of the neck and of the aponeurotic ring lengthen and break; the two openings, which were near, separate from each other, the former sinks, passing inwards, whilst the latter retains its place. Whilst the taxis is employed, the cone above the neck of the sac on its abdominal side becomes very prominent and much lengthened, is no longer formed as in the former case (where the neck of the sac adhered closely to the aponeurotic opening) by the whole thickness of the abdominal wall, but merely by the peritoneum, raised and detached from the muscles by the sac which endeavours to get between those parts. The sac re-enters successively and gradually through the abdominal ring as it dilates, and towards the end of the experiment it escapes suddenly and gets behind this opening. It is then easily felt through the abdominal walls by placing the finger on the spot which the rupture had occupied; it forms a large, hard, round chesnut-like tumour, deeply seated above the ring. Thus the reduction is complete, the rupture has returned *en bloc*, and is situated between the abdominal peritoneum and the posterior surface of the abdominal ring. The ring contracts slightly by its elasticity, as soon as the sac has entirely slipped above it, and to a certain point prevents the reappearance of the tumour externally. This reduction *en bloc* is sometimes followed by a slight rush, in consequence of the hasty passage of the bottom of the sac through the ring; but this rush never happens when the ring is loose and wide," in which case "the tumour goes in and out with equal readiness. The replacement in mass of a rupture, strictured by the neck of the sac, takes place most easily when the abdominal ring is of large size and short, when the sac and its neck are loosely connected to the surrounding parts, and when the protruded viscera adhere together, and to the sac, so that reduction in the usual way is impracticable. In one case of direct inguinal, and in another of crural rupture, I found that the tumour could only be returned in mass, although the neck of the sac was not narrow, in consequence of close adhesions between the protruded parts and their peritoneal covering."

These experiments of Cloquet upon the dead subject, pretty closely tally with Mr. Luke's general account of the accident in the living patient. And Mr. Luke further observes, "it is a circumstance worthy of remark that the firmness of the adhesions of the parts in which it is embedded, bears no proportion to the duration of the hernial protrusion, as might be, *à priori*, expected; for in all the cases of reduction in mass which he relates, the hernia had been of some years' duration, yet in each was reduced without the employment of much force."

This readiness to return, described by Mr. Luke, further confirms Cloquet's observations, and should warn the surgeon against too violent efforts in attempting reduction of a strangulated rupture. I doubt, however, that the connexion between the rupture-sac and its coverings is so slight as generally Mr. Luke's statement would seem to infer, for were it so, reduction in mass would be of daily occurrence under the unskilfully applied violent pressure so constantly employed, as is well known, in the ordinary use of the taxis.

In treating of the circumstances connected with the reduction in mass, Mr. Luke justly observes that "the too exclusive reliance upon the absence of tumour, as a sign of the non-existence of a hernia, may, in certain cases, be highly dangerous. In such cases more security will be derived from the institution of inquiries concerning the *previous existence* of a tumour in the part, and of its conditions when ascertained to have existed—such as its hardness, or the reverse; its freedom from pain, and also the amount of, and the manner of applying the force used for its reduction. By such inquiries, not only may the dependance of the symptoms of intestinal obstruction upon hernial strangulation be determined, but also the presumption of a reduction *en masse* may be raised or removed."

He also notices "that the presence of a sac, even without hernial contents, causes an abdominal fulness in the part, easily ascertained by examination. The absence of such fulness in a part where hernia is known to have previously descended, necessarily leads to the conclusion, that the sac, upon which it depended, has been displaced, and probably returned, together with the hernia. The sac in inguinal hernia below the external ring, becomes united with the spermatic cord, whereby the latter is usually rendered indistinct and obscure. The absence of that indistinctness and obscurity implies the removal of the cause which previously produced them, and, therefore, that the sac has been displaced. The continuance of the indistinctness and obscurity leads to a directly contrary conclusion. When a hernia descends from the abdomen, the aperture through which it descends is always enlarged and dilated. This fact is ascertainable by the introduction of a finger—a circumstance which becomes available to the diagnosis in these cases. Should a large aperture be detected, a previous hernial descent may be inferred. Under ordinary circumstances of hernia, when the contents are reduced into the abdomen, the area of the aperture is occupied by the remaining sac, whilst its margins are rendered more or less obscure. If, then, a large aperture be found free and unobstructed, with its margins unobscured, there is raised not only presumptive evidence of the previous protrusion of the hernia at the part, but also the further evidence of the displacement and probable return into the abdomen of the sac by which the hernia has been invested. We are led to a contrary conclusion by contrary circumstances."

Mr. Luke does not appear to lay so much stress upon the existence of a swelling within the walls of the belly, immediately above the internal ring, as from M. Cloquet's experiments and statements would be anticipated; for, though he observes "it may be expected that if such reduction has been effected, the inflammation of the hernial contents will cause a circumscribed pain in the part which it occupies, while a fulness, or even the rounded form of the hernia deeply situated within the abdominal parietes, may possibly be cognizable upon a minute examination, yet the absence, both of a circumscribed pain, and of fulness or rounded form, should not lead to a negative opinion; for in his first case neither pain nor fulness existed, yet, subsequently, a mass of strangulated intestine was discovered at the part. Their presence, however, may be taken as corroborative of an affirmative opinion, founded upon the manual examination previously instituted."

This statement of Mr. Luke's, in regard to the occasional absence of swelling, or, more properly speaking, its non-projection forward, is explained by a preparation already mentioned, in which an inguinal rupture had been reduced in mass; symptoms of strangulation continued, and the patient died on the fifteenth day. The rupture had existed many years, and the patient having worn a truss, suffered no inconvenience nor had difficulty in returning it, till one day, without assignable cause, it became tense and painful, and strangulated. The sac is pyriform, nearly three inches in its long diameter, situated between the abdominal and iliac muscles and the peritoneum. Part of it lies below the crural arch, and extends it nearly as far as the iliac vessels, and it forms a considerable tumour, projecting inwards towards the abdominal cavity, but is not discernible in front.

Dupuytren says, "that if the tumour be examined through the cavity of the peritoneum, it will be seen lodged in the iliac fossa—a little more outwards in crural—a little more inwards and deeper in inguinal rupture." And this difference of the kind of rupture may be the cause of the greater or less projection forward of the swelling, and its more or less ready discovery through the walls of the belly. In consequence also of its situation in the iliac fossa, he considers the sac has two layers of peritoneum in front of it—to wit, that portion lining the back of the abdominal muscles, and the other which spreads on the iliac muscles. Although this probably is so when a femoral rupture has been returned, yet it is not necessarily so as the peritoneum may be forced up above it, as it has been in the preparation of inguinal rupture just shown. But it is probable that the reduced sac may not rest at all in the iliac fossa, but may be thrust up before the peritoneum, between it and the abdominal muscles, as I have seen it, at least, when the sac has been returned during operations, in both situations; in one case, between the back of the peritoneum and the iliac fascia; and in another, between the front of the peritoneum and the transversal fascia; consequently, in the latter situation, it has not any additional peritoneal covering, but was immediately behind the abdominal muscles; and there does not appear any reason why it should not be so placed also when forced up without an operation.

Treatment.—When this untoward event is presumed to have taken place, the question naturally arises—can it be remedied? It has been advised that the patient should stand upright, and cough or strain, for the purpose of forcing the sac down again. But this seems little likely to be effected, on account of the immediate narrowing of the passage by which the rupture-sac has escaped from the belly. I have mentioned that Cloquet states that even in the dead subject, this opening contracts directly after the ascent of the rupture-sac, and to a certain extent prevents its reappearance externally. If this be so in the dead, it is still more probable that still greater contraction occurs in the living subject, and consequently the redescent of the rupture-sac is still less likely to be effected. Some other remedy must, therefore, be employed, "which," says Dupuytren, "consists in seeking for and drawing down the rupture by the opening through which it has passed into the belly, being assured that it will be found lying on the

internal surface of that opening, where it can be laid hold of with the forceps, and drawn out, with or without cutting the edge of the ring."

Now, whether the swelling can be distinctly made out, or whether there be only sufficient presumption of a reduction in mass having been effected, the operation should be conducted with great caution, as it has more or less of an exploratory character. It consists in cutting into the cavity from which the rupture-sac is presumed to have been thrust up. Most commonly, in inguinal rupture, the sac, whether full or empty, is situated in front of the spermatic vessels, which it conceals; if, therefore, when the cremaster muscle be cut through length ways, an empty space be found, behind which are the spermatic vessels, and into which the finger may be introduced and carried up into the belly through the rings and inguinal canal, and if this cavity be shreddy, and have not the shining and smooth appearance of the inner surface of the peritoneum then it may be presumed the sac has been thrust up and the cut must be carefully extended upwards till it can be reached, and then attempted to be brought down into the situation it had previously occupied When this is done it must be freely opened, the stricture fully divided, and the gut returned. If, on the contrary, when the cavity cut into is found smooth and polished, there is little doubt that it is the rupture-sac undisturbed, and the explanation of the symptoms of strangulation must be sought for in some other cause. But if, after cutting along the spermatic vessels, there be not any cavity, either shreddy or polished, if the finger cannot be passed into the belly, and if the spermatic vessels be found in their natural position and connection, then it may be presumed that there has not been any reduction because there has been no sac to return. The part to be selected for examination, and the extent of the cut, must depend upon the information obtained as to the extent to which the rupture is supposed to have reached; therefore it would be lengthways and lower in presumed scrotal rupture than when it has only been commonly protruded through the external ring, and still higher if it have not descended through the ring. When a femoral rupture is supposed to have been bodily returned, the character of the void, if any, and the capability of introducing the finger into the belly through its aperture, will show whether it be peritoneal sac opened, or merely the space which it had previously occupied; and if the latter, the finger must be passed up towards the belly, and the sac, if reachable, brought down and opened. But if there be no cavity of any kind, then it may be presumed that there has been no rupture down, and the cause of the disorder looked for elsewhere.

If the warm bath, bleeding, and the taxis be unavailing, it is advisable that the strangulated bowel should, as speedily as possible, be set free by a surgical operation. Other remedies have been proposed for use previously to operating, with the expectation of favouring the return of the bowel, but they are rarely efficient, and as delay is created by their employment, and no time can be spared when there is fair ground for believing that the operation will most likely be required, it is better not to make use of them.

I may observe that it is far from unfrequent to find patients labouring under strangulation drenched with purgative medicines, the greater part of which, if fluid, is rejected almost as soon as swallowed, and thus the vomiting rendered still more distressing. Occasionally the practitioner congratulates himself on finding that the stomach will retain calomel and colocynth, and hopes that the bowels may be relieved; an expectation, however, which will of necessity be disappointed, if it be bowel that is strangulated. The celebrated Monro primus says that he has more than once reduced a rupture with a smart dose of calomel and jalap. No dependance, however, can be placed on medicine given by the mouth, and therefore its administration that way is useless. Mr. Pott, however, observes, "Though I cannot say I have seen frequent benefit from the exhibition of cathartics by the mouth, yet I have often experienced the good arising from acrid stimulating glysters, and suppositories frequently repeated, particularly from the smoke of tobacco, and from a composition of salt, honey, and aloes, boiled to the proper consistence of a suppository. By these I have seen very alarming ruptures returned, when they have been thought capable of being relieved by nothing but the chirurgical operation."

Such is Mr. Pott's opinion in regard to clysters and it is reasonable to expect by exciting the action of the colon below the strictured part, more especially in those cases where part of that bowel is strangulated, that the gut may be drawn out of the sac, and thus reduction effected.

The use of tobacco clysters, in the proportion of a drachm of the herb to a pint of water, infused for ten minutes, half of which was to be thrown up and the other half after the lapse of half an hour if the first did not produce effect, has been strongly urged by many surgeons, and especially by Sir Astley Cooper. It is, however, a very uncertain as well as unsafe remedy; the great difference in the strength of the tobacco renders it uncertain, as with the same quantity of the herb its active principle may vary considerably, so that it either acts violently or not at all; it is also unsafe, as one person will bear without inconvenience a quantity which will almost extinguish life in another, owing to peculiarity of constitution. I do not, therefore employ this remedy, nor am I disposed to recommend it. The effect of a tobacco clyster is to produce squeamishness and great prostration of strength under which, certainly, attempts at a reduction are more hopeful. But the same effect is produced by a warm bath and bleeding more certainly and more safely.

Vomiting with tartar emetic has also been recommended, and I have seen one or two instances in which reduction has been effected whilst the patient has been suffering greatly from its depressing effects. But I should not employ it, for usually there is already vomiting sufficient, and the efforts made in that action are more likely to force down and increase the quantity of bowel thrust down than to favour its reduction, for it cannot very well be supposed that the bowel will be pulled out of the sac into the belly as the vomiting proceeds.

It must, however, be admitted that any or all of these remedies must be resorted to when the patient will not submit to an operation. In addition to these, cold applications have been made to the rupture-sac, to diminish the size of its contents by emptying its vessels of their blood, and by producing a sort of contraction in the skin, which shall gently constringe the sac and its contents. Monro primus was accustomed to apply cold claret for this purpose with success—a sad waste of good liquor, however, inasmuch as cold spring water would have been as efficient, if not more so—a good example of which is mentioned by Petit, who, having bled eight times a patient with strangulated rupture, and used other remedies without effecting reduction, was on the point of proceeding to operate, when the grandmother rushed in and prevented the operation, saying she would cure the boy in a minute. She then laid him naked on a coverlet upon the ground, and having separated his thighs, she smartly and suddenly dashed a bucket full of water fresh from the well upon his scrotum and thighs, and the cremaster and dartos being immediately excited, contracted suddenly and completely, and returned the rupture.

Ice, coarsely bruised and mixed with salt, in such quantity as to half fill a bladder, and laid on the swelling so that it wraps round it, is, however, more commonly employed; and if ice cannot be procured readily, a freezing mixture of hydrochlorate of ammonia and nitrate of potash, five ounces of each to a pint of water, may be put in a bladder and applied as a very efficient substitute. It is necessary, however, in using great degrees of cold, that the swelling should be carefully watched, or the skin may be found frost-bitten and slough, which occurred to a patient whom the elder Mr. Cline attended with Mr. Sharp. the ice in this case was applied for thirty-six hours, at the expiration of which time the skin became absolutely frozen, extremely hard and discoloured; when warmth was applied the redness and circulation were restored; and the contents of the sac returned with a gurgling noise. About ten days after the integuments sloughed off, but the patient did well.

Under favourable circumstances, after the reduction of a strangulated rupture, the symptoms generally subside: the vomiting ceases, the bowels, usually in a few hours, begin to act without or with the aid of medicine, and the patient is soon restored to health. But sometimes the peritoneum, and even the bowel, have become so inflamed that closely resembling symptoms still continue, and require corresponding treatment with calomel and opium, general bleeding, leeching and blistering the belly or the application of large light poultices; occasionally, indeed, such cases may prove fatal. The strangulation also may have existed such time that the bowel may be unable to recover itself, even when returned into the belly; and the patient dies.

The rule, therefore, in all cases of strangulation is, after failure of reduction by the taxis, assisted with warm bath and bleeding, to advise the immediate performance of an operation as the only mode of cure; and to impress on the patient's mind, that if performed early, it is little dangerous and generally successful, but that the longer it is deferred the less likely is it to be successful, on account not only of the increasing injury of the strangulated bowel, but the setting up or spreading of peritoneal inflammation.

SECOND SERIES.

Reported by THOMAS FRANCIS PANSON, of St. George's Hospital.

MEDICAL CASES.

CASE II.

Phthisis, with Pneumothorax.

George Murram, aged twenty-four, gardener admitted June 4th, by Dr. Wilson. Body emaciated countenance pale; iris blue; pupil dilated; lips thick; bowels sometimes confined, at others too much open; urine high coloured; appetite bad; tongue pale; pulse quick, but weak. He stated that he had had a frequent hacking cough for six months; that two or three times he had spat up with his cough small quantities of blood; that he had lost flesh greatly; and had perspired much. Within the last three weeks he had spit up more blood; had sometimes slight pain at the chest; constant night sweats; and had frequently found his ancles swollen at night.

He now complained of increased pain in the chest, and cough; it was a dry cough, but he had expectorated formerly.

Applic. emp. lyttæ sterno; Haust nitri. c., Vin. colchici, m. xv. ter die; Pil. scillæ c., gr. x. bis die.

June 5. On examining his chest, it was found to be very imperfectly expanded, even on deep inspiration, especially towards the apices; indeed, there was a marked depression under each clavicle. Sound yielded by percussion was short and dull in the same situations; becoming more resonant lower down. Respiration was generally coarse and tubular, and in some places, particularly towards the right apex, accompanied with a loud gurgling; here also bronchophony was very distinct. At the left apex, cavernous respiration, and pectoriloquy, were audible.

6th. He has now much less pain in the chest, and difficulty of breathing. Expectoration has returned; it is in thick rounded masses floating in a quantity of thin mucus.

Perst. in rem.

9th. Complains of much pain in the left side; there is increase of dyspnœa; decubitus on the right side; some anxiety of countenance. There appeared to be no motion of the affected side during respiration, while that of the opposite side appeared to be increased. The left side was also unduly resonant on percussion. All the former sounds had disappeared, except bronchophony towards the root of the lung; and in their place was heard amphoric resonance during breathing over nearly the whole side of the chest; and towards the inferior and posterior part was heard metallic tinkling of the voice.

Omit. rem.

℞. Calomel., gr. ij., Opii. gr. iss. bis die.

13th. Mouth not affected; but pain and dyspnœa less.

Perstet in med.

16th. Pulse 130; profuse perspiration; dyspnœa and pain in side much increased; decubitus towards left side, which is now found to be quite tympanitic, except at the lower third, where a dull sound is given; metallic tinkling has also disappeared; heart displaced, and seen beating to the right of the sternum.

M. s. ad ℥ viij.

17th. Fainted yesterday while being bled, so that the proper quantity could not be taken. Pulse weak and rapid; face livid; dyspnœa and difficulty of expectorating much greater.

Sp. æther, sulph. ♏. xxv.; Mist. camph. c. h. nitri., āā ℥ vi. ter die.; Vin. rubri. ℥viij. ex. aq.

Became delirious in the night, and died before morning.

AUTOPSY SIXTEEN HOURS AFTER DEATH.

Thorax.—On opening the chest a large quantity of air escaped from the cavity of the left pleura. The left lung was driven against the spine, where it was compressed by a large quantity of thin, puriform fluid, mixed with masses of lymph. Both layers of the serous membrane were very much thickened, and covered on their free surfaces with recently effused lymph; the lung itself was, throughout its whole extent, thickly studded with miliary tubercles and vomicæ, some of which were situated close to the pleura; and one of the vomicæ at the anterior part of the lower margin of the inferior lobe had opened into the pleural sac; the opening being about the size of a sixpence, with thick, elevated margins, and covered over with a false membrane. In the apex of this lung was a vomica of the size of an orange. The right lung was also thickened, with tubercles and vomicæ, several of which, especially towards the apex, were situated immediately beneath the pleura, but had not opened into it. The pericardium and heart were pushed over to the right side by the effusion into the cavity of the left pleura. The heart itself was healthy throughout.

Abdomen.—Kidneys large, soft in texture, and coarse in structure. Some of the mesenteric glands were enlarged, and several ulcerations, with tubercular deposits in the neighbourhood, existed in the mucous membrane of the intestines, especially in the appendix cœci. Nothing remarkable in the liver or spleen.

REMARKS.

On this patient's admission he presented well-marked symptoms of phthisis, in rather an advanced stage, and which might be expected to run its course more quickly than otherwise. But an accident soon occurred which tended greatly to aggravate his previous distresses, and to hasten his death: this was the perforation of the pleura by one of the vomicæ. But, as the phthisical lesions were the cause of the accident, it will be right for me first to consider some of the phenomena presented by that disease. As, however, in a preceding case, I have attempted to give a sketch of the first formation of tubercle, I shall now pass on to a consideration of the stage of softening and its consequences, as they occurred in the present case.

When tubercles have existed for some time in the lung, they begin to excite irritation and inflammation in the surrounding texture, from the constant pressure which they keep up. This inflammation, occurring in scrofulous individuals, is essentially of a scrofulous character; serum and thin pus are effused, which soften and break up the crude mass, and convert it into the soft, curdy, grumous matter of the mature tubercle. An ulcerative process is at the same time going on in the surrounding texture, so that several of these masses coalesce, to form one of much larger size. The inflammation, still continuing, keeps up the effusion of lymph and pus, and at last this purulent dépôt, mixed perhaps with the tubercular matter, is partially, or wholly, coughed up through the air passages, and a cavity or vomica is left.

If an opportunity occur of examining a vomica at this period, its surface will be found soft and ragged, and, perhaps, of an irregular form, from the union of several smaller ones having taken place. Its size may vary from that of a pea to that of an orange, or even larger; but these large ones only occur in the upper lobes. Opening into the cavity may also be seen some pervious bronchial tubes, which, from their not having possessed any elasticity, so as to be pushed aside by the tubercular mass, have shared in the ulcerative process, leaving their open mouths, by which the softened matter may find an exit. But a blood-vessel seldom or never opens thus into a vomica, and a most happy circumstance indeed it is, for fatal hemorrhage would certainly instantly occur. The reason why these vessels do not open into the excavations is because, from their structure possessing more elasticity, they are easily pushed aside by the tubercular mass; the blood then being obstructed in its passage, coagulates, and the vessel becomes obliterated for some distance beyond the seat of the morbid process. Occasionally bands are seen intersecting the cavities in various directions; these are said by some to contain blood-vessels, but they are almost always impervious.

Some of these appearances were met with in many of the numerous vomicæ with which the lungs of our patient (Murrain) were so thickly studded; but one of these especially presented several points of interest, its situation in the apex of the left lung being the point where the tubercular deposit generally first takes place, and where the process of softening first commences. Its size and shape being large, and of an irregular form, would lead to the supposition that it was formed from several smaller ones having coalesced, so as to form one of large size. It was also partly lined with a thin membrane, giving rise to the idea that it had existed for a longer time than the others. This membrane consists generally of albuminous lymph, mixed, however, with tubercular matter, and for this reason it never remains entire for any length of time, but gradually becomes detached and expectorated.

This leads me to speak of a way in which cavities may (though it very rarely happens) become obliterated. If there be no tubercles or cavities in the vicinity, and the powers of life are strong, the lining of the cavity becomes organised; the bronchi, by some plastic process, are rendered impervious, so as to prevent the ingress of air, which would otherwise hinder the contraction; the vomica then collapses, presenting the appearance of a cicatrix, and attended with a puckering of the adjacent pleura. But these cicatrices generally contain a small quantity of a pale-coloured, hard, earthy matter, which may have been secreted by the lining membrane; but it is more probable that it results from the earthy insoluble salts of the contents of the vomica remaining after the animal matter has been absorbed. This, however, as I stated before, is a very rare termination of phthisis; much more frequently, the vomicæ increase both in size and number, until the patient dies, worn out by exhaustion, or asphyxied by due aeration of the blood being prevented or cut off by some intercurrent inflammation; or, perhaps, from the combined effects of some or all of these. This happened to our patient in the present instance: probably his existence might have been prolonged for some weeks, had not perforation of the pleura taken place, and occasioned that worst form of pleurisy, pneumothorax.

In the majority of persons who have tubercles or vomicæ, and more especially if they are situated near the surface of the lung, dry, or adhesive pleurisy is excited by the constant irritation which they keep up; this is the reason why perforation of the pleura is so rare; because, in the vomicæ near the surface, the part is secured by previous adhesion. But when it is not previously secured, it is from a want of plasticity in the products of inflammation, and a low state of the reparative powers: such a state as one might, à priori, have expected to find in our patient, from the appearance he presented.

Immediately on the communication being established between the vomica and pleura, the air rushes in at each inspiration, irritating the pleura, and causing dyspnœa; however, as the opening was pretty large, it afforded a ready exit for the air during expiration, and so did not cause such immediate collapse of the lung as it would have done under the opposite circumstances. Affairs might have stood in this condition for some time, had not the pleurisy caused an effusion of lymph, which blocked up the perforation, and thus prevented the egress of the air, permanently collapsing the lung. It seemed, in fact, as if nature had become aware of the fault which she had committed in not throwing out lymph before hand, and had endeavoured to accomplish that object when it was too late; the consequences were fatal to the patient, for the air remained, and sero-purulent matter was secreted in considerable quantity, until the lung became completely collapsed; and the opposite side not being adequate to its increased duties the continuance of life was impossible. The puriform effusion was such as might be expected in a feeble, scrofulous patient like ours; but it may be said that the effusion of lymph must have indicated a degree of power in the system; but it was rather owing to one of those fierce, unequal, and transient flashes of inflammation (excited here by the presence of air in the pleura), which are so often seen towards the close of phthisical cases.

The lung was found pressed flat up against the spine in the form of a thin cake, but capable of being restored to nearly its former volume by insufflation through one of the principal bronchi. Another point in the morbid anatomy was the existence of tubercular disease in the abdomen also; this is of very frequent occurrence, and proves the assertion that phthisis is not only a pulmonary disease: Louis met with it in five-eights of the fatal cases which he examined.

The history which this patient gave was very unfavourable; he had had a slight cough for months, for which he could not assign any reason; he had spit blood, showing that some obstruction to its free passage existed in the lung; he had night sweats, and diarrhœa, which we afterwards proved to be occasioned by ulceration in the intestine; there was emaciation; œdema of the ankles. This last symptom, Dr. Watson says, tells us that the disease is about to terminate, and is therefore valuable as a prognostic sign.

His *general* symptoms on admission gave us pretty positive proof of the nature of his complaint. There were quick pulse, and other indications of hectic, giving evidence of irritation in some part of the system. The nummular woolly-like mass of sputa, which seldom appear except in phthisis. The dyspnœa not absolutely painful, but more a state of breathlessness. His *physical* symptoms confirmed our diagnosis, and showed that he had both tubercles and vomicæ. We found portions of both lungs, especially the upper parts, in a state of consolidation, as evinced by the dulness on percussion, the bronchial breathing, voice and cough. In other parts a bubbling, gurgling sound told us that some of the consolidations were breaking up, and cavities forming. Again, cavernous respiration and pectoriloquy told us that in one spot the tubercular and purulent matter had become evacuated, and that a cavity was left.

We had not had an opportunity of observing these phenomena for many days, before new and equally interesting symptoms arose. There was undue resonance of the left side of the chest, which had before yielded a dull sound; all the previous auscultatory signs had vanished, except at the root of the lung, where strong bronchial breathing was audible, from the circumstance of the lung being tightly pressed against the larger bronchi, and thus affording a solid conducting medium. But the most strikingly characteristic sounds were the existence of amphoric resonance, and metallic tinkling. This may proceed either from the reverberation produced by the air in the distended cavity, or else by the air passing in bubbles through the liquid, which its presence has caused to be effused. The liquid does not seem necessary for its production, as we had not at first any physical signs of its presence, and, indeed, when we had, the sound had ceased, though that was caused undoubtedly by the closure of the aperture.

The ordinary general symptoms of pleurisy were also present. One of these perhaps I may glance at, because considerable difference of opinion has existed with respect to it—I mean the *decubitus*. The patient at first lay on the sound side, afterwards towards the affected side. This is what Dr. Watson has most frequently witnessed, and he explains it in the following manner:—"At first the patient cannot lie on the affected side, on account of pain; but when the pain has ceased, and effusion taken place, the pressure of that would impede the motions of the sound side, and he therefore takes a diagonal posture—i.e., on his back, but towards the affected side."

These general symptoms were not, however, in such a marked degree as the sudden irruption of air generally causes. When the aperture is small, so as not to allow a free egress to the air, the patient may be speedily suffocated, unless artificial assistance be given; and when the aperture is large, as we presumed in this case from the amphoric resonance, the constant rubbing, as it were, of the air against the surface of the pleura in its passage to and fro, generally excites a great deal of inflammation; this, however, passes off after a time, and the patient may live for months after, with tolerable comfort, if he have sufficient lung remaining sound. But it was not to be so with our patient; for after a time violent inflammation was excited, perhaps from the air becoming suddenly confined in the sac; liquid effusion was soon added to this, as we found by the dulness of the lower part of that side of the chest; his pulmonary apparatus became thus too far deranged for the further continuance of life; and he died.

The treatment adopted on his admission was entirely palliative. Colchicum and squill were given to increase the secretion of the pulmonary mucous membrane, the stoppage of which had given rise to congestion; and also to procure more ready expectoration of the secreted matters. On the supervention of pneumothorax, mercury was given, in order to check the pleurisy which was with reason expected. The disease, however, pursued its course for some days almost silently; at last it burst out with fresh violence; blood-letting was prescribed to mitigate the urgency of the symptoms; he was found to be in such a low state, however, that it dare not be proceeded with; so quickly did he sink, that the slight operation of paracentesis thoracis seemed to hold out no hope of relief.

MANCHESTER EYE HOSPITAL.

By A. W. Close, Esq.,
Grosvenor-street, Machester,

Mr. Lawrence's Cases of Gonorrhœal Ophthalmia; Observations on the proper Mode of using the Arg. Nitr., and of its effects.

Locke has written a learned chapter on the "Association of Ideas." He has it, that "There is a connection of ideas wholly owing to chance or custom; ideas that in themselves are not at all of kin, come to be so united in some men's minds, that it is very hard to separate them; they always keep in company, and the one no sooner at any time comes into the understanding, but its associate appears with it." Under some such psychological spell, I thought, on reading Mr. Lawrence's clinical lecture on purulent ophthalmia, "Had he been as faithful to his early medico-political principles and notions, as he has been to the antiphlogistic mode of treating this disease, how different would have been his past career and his present position!" What he was in the beginning, is now, and shall be hereafter, I will not stay to set forth. In many cases, one with amazement hears the arguings, and is astonished at the obstinacy of a worthy man, who yields not to the evidence of reason, though laid before him as clear as daylight. This sort of unreasonableness is usually imputed to education and prejudice, and for the most part truly enough, though that reaches not to the bottom of the disease, nor shows distinctly enough whence it rises, or wherein it lies. Education is often rightly assigned for the cause, and prejudice is a good general name for the thing itself; but yet, I think, he ought to look a little farther, who would trace this sort of madness to the root it springs from, and so explain it, as to show whence this flaw has its original in very sober and rational minds, and wherein it consists.

In Mr. Lawrence's clinical lecture his observations are founded on five cases of gonorrhœal ophthalmia, which were treated first antiphlogistically, and then by the local application of argent. nitrat. Acquainted as he must be, or ought to be, with the opinions of O'Halloran, Guthrie, Walker, Ridgway, Littell, Ricord, and a host of others, on the stimulant treatment (I use this term as being in general use), it is surprising that he has not long ere this given it a satisfactory trial. I am sure he could not intend fairly to test its virtues in the cases here reported.

In case No. 1, the solution, containing four grains of arg. nitr., in one ounce of aqua, was ordered to be dropped in night and morning. The report says, "The first drop produced no particular effect; the second made the eye feel hot and uncomfortable," and on that account it was altogether dispensed with. This was on the 16th of May. On the 12th of the following month, "He left the hospital, well."

In case No. 2, "A solution of the nitrate (gr. j, ad ℥j.) was ordered to be dropped into the eye, and repeated in the evening if found beneficial." The report of the following day states, "The solution was dropped in last night, and the eye felt easier: it was not repeated at bed time." Why not? "It was again dropped in this morning with unfavourable effect." Indeed! what a potent agent the one-grain solution must be!—what homœopathic virulency it possesses! No wonder it was discontinued.

No. 3.—The solution, grs. ij ad ℥j, was ordered to be introduced between the lids two or three times a-day. The report on the following day is, "The swelling of the lids and the chemosis are diminished; the pain in the eye is much relieved" The next day, "Progressive improvement. The caustic solution gives no pain." Not being satisfied with the improvement, although progressive, the solution was made of double strength. The next report is, "The first application of the stronger solution caused so much pain, that it has not been repeated this morning." Some eighteen or twenty leeches were afterwards applied, and two days after the two-grain solution was again used, and the eye went on well"

Case 4.—On the fifth day after the admission of the patient, "the stick of nitrate of silver was passed over the prominent chemotic swelling of the conjunctiva." On the following day it is remarked: He "slept well; eye less painful; the tumefaction of the lids and the chemotic swelling considerably diminished; the discharge lessened in quantity." This was on the 19th. Well; that tells bravely for the sadly maligned nitrate. But, oh ye powers! On the 20th was discovered what nobody ever saw before or will see again. "The cornea is become opaque towards its central and lower portion, for about two-thirds of its surface." Does the erudite lecturer wear spectacles? This change in the cornea is attributed to the escharotic. On the 9th of the following month it "was now discovered that a broad and close adhesion of the lower eyelid to the globe had taken place near the external canthus."

Case 5.—A solution, gr. x ad ℥j, was tried which caused a severe smarting pain for an hour; afterwards slept well." It was repeated on the following day; omitted; the chemosis excised, and then the stick of nitrate was passed over the tumid conjunctiva; prolapsus iridis ensued, and so the matter ended.

In all the cases, the antiphlogistic treatment by cupping, leeches, ant. tart., &c., was first adopted. Mr. Lawrence proceeds to relate two or three cases where individuals had presented themselves at a public institution, nothing at all being, in fact, the matter with their eyes, and having had some stimulant applied to them, inflammation had been set up. One severe case arose from "a small particle flying into the eye, as a person was scraping a stick of the caustic to a point." The inflammation so excited he is pleased to define, "lunar caustic ophthalmia." No doubt the size of the next edition of his "Treatise" will be increased by a lucid description of this new disease. We shall be happy to furnish him with cases of "steel filing ophthalmia," "granite ophthalmia," "lime ophthalmia," "sulphuric acid ophthalmia."

He then gives, and we are glad to get so much from him, two cases to show that the two-grain solution of the nitrate dropped into the eye, two or three times in twenty-four hours, "will cut short catarrhal, and even the milder forms of purulent ophthalmia."

Now, I believe any unprejudiced observer, from the mere outline I have given, and more particularly from the perusal of the document itself, must be struck with the utter pusillanimity, indecision, tergiversation, of the whole affair, so far as the nitrate is concerned The cases prove nothing against, but perhaps something for it. Observe the marked improvement in case No. 4, on the 19th.

It is not my intention at present to say anything as to the use of the arg. nitr., either in solution or ointment. Such applications are seldom properly applied by the patient or his friend. The substance has the advantage of being always applied by the surgeon himself. I am aware that it is very easy at all times to make an assertion—often difficult to support it. But with the full intention of elucidating the statement, I hesitate not to say that all the five cases might have been much more expeditiously and satisfactorily cured by the early and proper application of the arg. nitr. in substance, and that probably without the loss of a drop of blood. If properly used, it never did, never will, produce either opacity of the cornea or symblepharon. These effects in the cases related, either resulted from the disease itself or from a very injudicious manipulatory manner of applying the remedy. I have consulted M. Ricord's work, with special reference to this particular; no such effect is mentioned. "This gentleman," Mr. Lawrence observes, "who has great experience in the treatment of gonorrhœal ophthalmia, uses the nitrate of silver, in substance, in all cases, as he alleges, with invariable success." Be it observed, as to all the allegations we may make, we give a hearty invitation to any surgeon who pleases to come and see for himself, any Wednesday or Saturday morning, at twelve o'clock, a. m., Eye Hospital, South Parade.

Superficial ulceration of the conjunctiva sometimes results from the use of the nitrate. On this Mr. Walker says, "In the vast majority of cases this ulceration is followed by no disagreeable consequences—it is a matter of no importance; indeed, in some instances, it is probable that it may be rather beneficial than the contrary. Yet it occasionally happens that slight inversion of the lid results from it. It has fallen to my lot to witness some hundreds of cases (now thousands) in private and hospital practice, in which the nitrate of silver, in substance, has been employed, and I do not remember to have seen more than two or three cases in which inversion of the lid occurred, and this, in all of them, was so inconsiderable as to admit of being easily remedied. This, as far as I know, is the only solid objection that can be raised against its use." Mr. Walker never saw symblepharon or opacity of the cornea produced by it.

The solution, after it has been used for some weeks or months, is very apt to stain the conjunctiva of a deep olive colour, which when it occurs in young persons, is usually regarded as disagreeable.

Having alluded to Ricord, let us claim for Mr. Walker that which is his due. This I will do in his own words, which will also embody the proper mode of using the nitrate:—"It is my opinion that the antiphlogistic treatment of purulent ophthalmia is both useless and improper. I have never myself employed bleeding, either generally or locally, in any of the cases of this affection which have come under my own care within the last thirteen years. Having for some time previously been in the habit of witnessing the admirable effects of stimulants in the treatment of some other varieties of conjunctivitis, it seemed to me that they might be equally serviceable in the disease in question; and I believe I was the first to employ the nitrate of silver, *in substance*, in this variety of ophthalmia; at least no published statement of any such employment of it had appeared at the time when my paper, detailing some cases in which it had been successfully used, was published (in 1830). The result, as regards my own mind, from my practice with this article in substance is, that I have great confidence in my ability to check by it the progress of the affection; and, at the same time, a conviction that very few, if any, cases of it will terminate unfavourably if this treatment be resorted to before any deep-seated ulceration or sloughing has commenced. The application of the nitrate in substance is easily made. Expose the conjunctival surface of the inferior eyelid, and then draw the stick, pointed like a pencil, *lightly* across it. The application is always productive of increase in the lachrymal discharge, and a severe smarting sensation, which usually continues from half an hour to three or four hours At the expiration of that period the uneasiness subsides, and

a decided improvement is soon perceptible in the condition of the eye."

It is now my duty to present, with a proper regard to the *ne quid nimis*, cases which will speak the *pro et con* for themselves.

I would add that my own observation leads me to think that it ought to be emphatically laid down as an axiom, that if the arg. nitr. be employed, it should be in substance, and at the *commencement* of the disease, or when the patient is first seen. It should be the *sheet anchor* rather than the *dernier ressort* or *coup de grace*. The solution as the disease disappears may become a very good substitute or accessory.

It ought generally to be applied only to the conjunctival surface of the lower eyelid. It ought not to be kept in contact with that texture for a moment, but should be *lightly, evenly*, and with *one* stroke carried along its surface. So used, it is a mistake to apply the term escharotic: it forms no eschar—destroys no structure—the vessels of the membrane, and the membrane itself, remain unabraded—it acts upon the mucous secretion and tears—producing, it is said, with these a chloride of silver, and turning the conjunctiva white: this soon vanishes.

TRANSACTIONS OF LEARNED SOCIETIES.

THE MICROSCOPICAL SOCIETY OF LONDON.

At the last meeting of this Society a paper was read by George Busk, Esq., F.R.C.S.E., on the "Structure and Nature of the Filaria Medinensis, or Guinea Worm"—a disease which the Emperor Henry V. is said to have died of, having had it from his birth.

The author of the paper commenced by observing that the subject of parasitic diseases, and the study of those morbid affections of both animals and plants which were caused by the attacks of parasitic organisms of one or the other kingdom, was so intimately connected with microscopic research, and depended for its ultimate and complete elucidation so much, or it might be said, so entirely, upon the application of the microscope, that the following observations relative to one of the most important parasites of the human frame might not, be considered altogether foreign to the objects of the Microscopical Society.

The author stated that having enjoyed many opportunities of observing instances of the occurrence of the guinea-worm in this country, he had arrived at some conclusions with regard to it which, if found to be correct, would be of interest not only in the particular instance of that worm, but which might perhaps by analogy apply to a much greater extent among the nematoid entozoa. The subject, however, as it related to the filaria medinensis, could not be pursued to the full extent in this country, nor in Europe, it being reserved for the observer in Africa or Asia to fill up the great gaps which, the author believed, yet existed in the complete history of this very troublesome parasite.

As from the rarity of the occurrence of the guinea-worm in this country, few, even among medical men, can be presumed to be very familiar with what is already known regarding it, the author before entering upon the proper subject of his paper, as it concerned microscopic research, briefly adverted to a few of the main points connected with the natural history of the entozoon, which tended in some degree to confirm the conclusions to which he was disposed to arrive from considerations derived from its anatomical structure.

The filaria medinensis, or guinea-worm, was stated to be an extremely common parasite of the human frame in those parts of the world where it was endemic. Fortunately, however, these parts were neither numerous or very extensive, being chiefly certain regions of tropical Africa and Asia. The proper habitation of the worm is in the torrid zone, but it was not confined to that zone, nor did it even occur in all tropical countries. Künsemuller, stated that it was to be met with in Arabia Petræa; on the borders of the Persian Gulph and of the Caspian Sea, on the banks of the Ganges, in Upper Egypt, Abyssinia, and Guinea; from its frequency in the latter country its vulgar name is derived. In some districts on the coast of Africa almost every native coming off to the ships was found to be affected with the worm, whilst in other places distant only a few leagues, scarcely a trace of it was to be met with. The same narrow range has been also observed in India, and the epidemic prevalence of the worm has been supposed to be connected with the periodicity of the seasons. In India, it has been stated by some writers to prevail mostly in the months of November, December, and January; correct observations, however, with respect to the point of *periodicity*, were much to be desired, with reference not only to this, but to all entozoa. In America the guinea-worm is unknown, except in persons who have had communication with Africa, or other parts where it is indigenous. The island of Curaçoa is the only locality in the new world offering an apparent exception to this fact, which it would be highly desirable to ascertain the real state of in this instance.

Though endemic only in the above-mentioned parts of the world, it would yet appear that all races of mankind were obnoxious to the attacks of the filaria when exposed to what might be called the contagion, that is, when placed in circumstances under which it might be supposed a contagious *seminium* could be conveyed to them. This liability was incurred, so far as the author had been able to ascertain, by the exposure of the bare surface of any part of the body to water in which the infection might be supposed to reside, there being, at all events, no evidence at present of any other source of infection. Mr. Busk stated that he had known many instances tending to prove that it was not necessary that a European on the coast of Africa should become infected with the guinea-worm by going ashore, it being quite sufficient for him to have exposed the bare surface of some part of his person to the water in the native canoes alongside.

The mode of its introduction accounts for the frequency with which the legs and feet are attacked by this parasite in preference to other parts of the body, as it would always, the author believed, be found that the men who had become so affected had been in the habit of going about with bare feet, which is common among sailors in warm climates. That the contagious material is conveyed in water is also further indicated by the well-known fact that, in India, where it is the custom for the natives to carry water in skins on their backs, the worm makes its appearance on the back, shoulders, and upper part of the body.

The entrance of the worm into the body was stated to be unattended with any observable symptom, the person affected being unconscious of its presence, until the period when it was ready to make its exit. Mr. Busk observed that the life of the worm might be divided into two periods, and its existence as a whole, or until, as he supposed, its cycle of development was completed, presented at least three, and it might be four, periods or phases; its parasitic life might be divided into one portion in which the worm is latent, and another when it has manifested its existence by external symptoms. The former lasts for a period of from twelve to eighteen months, during which period the worm resides in the cellular tissue, where it does not appear to exert any irritating influence upon the surrounding tissue, no mark of inflammatory or other morbid action being observable on the surface to indicate the locality of the worm. When the period of ripening, as it might be termed, arrives, the worm makes its presence known and its intended exit by perforation of the skin, and various other symptoms, the point of exit being usually marked by circumscribed inflammation, and its prolonged and tedious extraction being accompanied throughout by a great amount of suppuration and pain, according to the mode in which the artificial extraction is proceeded with, which, we believe, is effected with the greatest safety by the patient himself, who generally (having secured the head) winds it round and round a piece of twisted paper at a rate of, as stated by the author of the paper, from one inch to one inch and a-half a-day, until, as Mr. Busk affirmed, upwards of six feet of this intolerable nuisance were extracted; should, however, the patient in extracting it happen to break the worm, the portion left behind gave rise to ulcers of a most disagreeable character, and very difficult to heal.

The whole worm, when mature, was stated to be of a transparent, milky-white colour, presenting an indistinct brownish, wavy streak, running down it longitudinally; it is cylindrical, and about one inch and a half in diameter. Mr. Busk stated that Professor Owen, in the Cyclop. of Anat. and Phys., vol. ii, p. 122, remarked that the caudal extremity of the male is obtuse, and ends in a single spiculum, and even gave a figure of such an individual; but the author could not help thinking that the appearances presented by the caudal extremity in the instance alluded to were referrible to some unusual attenuation of the acuminated point in a worm of the usual kind. No anal or other orifice was perceivable at the caudal extremity of the worm, or any part of its extent; the author therefore believed none existed. The outer integument is described as being white, semi-transparent, firm, and of considerable thickness, highly elastic and extensible, and marked externally with transverse rugæ. Immediately within this elastic integument, two fasciculi of muscular fibres, not marked with transverse striæ, are placed on each side of the body, extending uninterruptedly from one extremity of the worm to the other. The author stated that there was no vestige of any ovarian tube, and the only apparent outlet for the young was the open extremity of the parent; consequently, it would appear that the rupture of the body was necessary for the escape of the offspring, which are described as being amazingly numerous, constituting, in most instances, the bulk of the contents of the animal's body; when expelled they are described as being scarcely visible to the naked eye.

Mr. Busk gave a curious instance of the tenacity of life of the filaria medinensis, which, he stated, would revive after having undergone a considerable degree of dissection. In the case alluded to, in which extraction of the worm from the body of a patient was going on by the man himself, whilst one evening pulling at it, he broke off a portion about four inches in length, and in order to preserve the worm for the purpose of showing it to the author, he placed it between the leaves of a book, and on the following morning it was found quite dry and flattened. Being desirous of examining the structure of the worm, this dried portion was placed in some lukewarm water in order to soften it. On looking at it a short time afterwards, Mr. Busk was much surprised to find it in active motion, which continued for some hours.

The above paper, and those of Messrs. Gulliver and Quekett, reported in this journal only, are the three most practically important papers read at the Microscopical Society during the present session.

REVIEWS.

Letters on the more evident Changes which the Body undergoes, and the Management of Health from Infancy to Adult Age. By C. Black, M.D. Post 8vo., bound, pp. 138. Whittaker and Co.

This is an unpretending little volume, chiefly addressed to the profession and the educated public. To the former it presents nothing not already known, and yet it embodies in the compass of a few pages a great amount of very valuable material; to the latter it commends itself chiefly, because the facts and inferences with which it abounds are such as cannot fail to prove useful to all who may choose to obtain and apply them. Many of the precepts are of excellent construction, and the whole shows the author to be well read in the most recent and important discoveries in the auxiliary sciences of his profession.

Whilst, however, we gladly pay this tribute to the meritorious parts of the work before us, we cannot, in justice, pass over certain passages of its literature without an unequivocal expression of dispraise. Here, for instance, is a ridiculous rhapsody:—

"Here I close my remarks on this important period; here, also, I take a temporary farewell of my subject. But few shall be the matin songs that shall swell on the breeze, and short the flickering

of the glow-worm's lamp, ere I return to my task, and once more revisit this harp of ten thousand strings, again to strike its silvery chords—again to interest you with the harmony of its notes, and to excite your mind to reflect on this masterpiece of creation—man!" (p. 62) Now, all this tapestry of verbiage, to tell us the subject would be resumed on some future occasion, seems very much like a piece of unnecessary trouble.

At page 117, and just over the leaf, we have the following:—

"Notwithstanding the vast—the sublime attributes of the Deity—and the apparent insignificance of those with which the mortal mind is endowed, great and merited praise obtains to that person by whom one seemingly hidden path of Omniscience is discovered, in which his imperishable footstep is exhibited amidst the *overwhelming shadows* of *celestial light*." Dr. Black's head must have been topsy-turvy when he committed this freak of authorship.

A little lower down, in page 118, is a specimen of rhapsody running riot after this style:—

"Shortly after this, the sun of knowledge proudly and majestically appeared above the murky horizon of medical science, and although its effulgent beam was for a time intercepted by the tenebrious mist in which the mental world was enshrouded, it still continued its upward course in the heavens, till, from its meridian height, it no longer shone upon a single vesture of its recent pall, but, with meteoric splendour, shed a lasting halo around the head of its illustrious discoverer." That a man of Dr. Black's scientific competency should string such arrant nonsense as this, is really too bad. The habit of writing in this mock-heroic strain is a growing one in our profession, and we grieve to see it. We earnestly desire to see good, substantial, and simple English, a feature in our national works; and our future authors may assure themselves that, in proportion as they deviate from this, in that very proportion will we punish them for their literary barbarities.

TO CORRESPONDENTS.

S. D.—*There is no law prohibiting any class of persons from commencing business as druggists.*

N. *should apply to a properly qualified medical practitioner. We make it a rule never to answer questions which demand a professional opinion of any kind, as we conceive such conduct would be treachery to the rights of our professional brethren. Medical opinions, from the case with which they are obtained, are generally esteemed too cheaply.*

Chirurgus *must form his own opinion respecting the value of the degree in question; any answer from us would be invidious.*

Why does not A Constant Reader *obtain the licence of the Apothecaries' Company? At present he is certainly liable to prosecution.*

Mr. Morris *will excuse us for the present. Our crowded pages, and the frequent publication of enlarged numbers, are, we should think, sufficient proofs of our desire to afford the profession information of the most valuable quality—by no means stinted as to quantity.* Mr. Morris, *we have no doubt, notices that original communications are at present almost entirely omitted to make room for lectures, and that even of these we have more courses under publication than we are able to continue every week, in consequence of want of space—the* Medical Times *being already the largest medical journal published in Europe. At a future period, however, when some of our present engagements are concluded, we hope to be able to oblige Mr. Morris and many other correspondents, to whom at present we can only offer a general apology.*

We are so frequently asked as to an eligible house for lunatics, that to avoid much unnecessary correspondence we may say at once that we have no personal acquaintance with any establishment of the kind, except that presided over by Dr. Costello, which, to our convictions, answers, both as regards site and administration, all the requisites of a model asylum for lunatics.

A. B.—*In our last* Pharmaceutical Number.

M. D.—*We think not. Giessen diplomas are in future only to be obtained by submitting to examination, thanks to the* Medical Times.

Mr. Startin's lectures will be continued in our next.

A Young Surgeon —*Chelius'* System of Surgery, *translated by South, will suit our correspondent's views.*

Many letters of correspondents are unavoidably postponed till our next number.

THE MEDICAL TIMES.

Saturday, May 16, 1846.

> An' if a man did need a poison now,
> Here lives a caitiff wretch would sell it him."
> Shakspere.

Ever anxious to maintain the interests of the General Practitioners, we feel called upon to notice, at some length, the covert attempts which the Pharmaceutical Society are now making to gain the support of the public and the profession, for the provisions of a bill to regulate the practice of their members They are walking cautiously and deviously to their object; but, nevertheless, have not been able to conceal their tortuous proceedings from the censor's eye. We should have refrained from descanting upon the subject at present, if our contemporary, the Medical Gazette, had not, last week, in one of its usual twaddling, yet insidious, articles, advocated the cause of the druggist, and advised the enactment of this bill prior to any legislation for the General Practitioners.

This policy may very well accord with the wishes of the few pure physicians and surgeons, who still hang on as patrons of that journal; but it would be most pernicious to the interests of General Practitioners. There can be no doubt that the consulting practitioners of this metropolis would willingly play into the hands of the chemist, with whom they are already leagued by practice and usage; and would rejoice at any measure of legislation that promised to embarrass or defeat legislation for our own profession. It may accord with their sympathies, principles, and interests; they have shown themselves, during the whole of this struggle, the enemies of the General Practitioners, and we are not surprised to find them the suggestive advocates of a measure which, *in its present form*, would be advantageous to themselves, but highly injurious to the great body of the profession.

It may suit the physicians and surgeons that chemists, who prepare their medicines, should be educated even higher than these duties absolutely require. But will it be satisfactory to the General Practitioners? We think not. Education is a great boon; it is daily claiming its rights, enforcing its authority, overturning all timeworn, exclusive and obsolete institutions, and reorganising into unity and vigour, all the discordant elements that have hitherto checked, though transiently, our social advancement. Order is the characteristic of our day. Education has broken up the components of a past state of society, and, having scattered them asunder, it is now, magician-like, reuniting them into new forms, and building up new systems from a disrupted chaos. We feel the power—we own it—and we are the last persons to struggle against its resistless dominion.

We object, however, to that scale of education that may be above the standard that particular duties require, yet far below the standard which other duties, individuals may be tempted to execute, demand. The Pharmaceutical Society wish to examine their members in *materia medica, botany, toxicology, &c.*, as matters relevant to their business as chemists and druggists. It may be so; but we defy a man to study materia medica in a proper manner without dipping into therapeutics, and hence into the whole domain of physic, so far as it is required for merely practical purposes; and toxicology directly leads to a knowledge of the effects of poisons on the system, which involves a certain knowledge of morbid anatomy and of disease generally. Will the Council of the Pharmaceutical Society invent a scientific bed of Procrustes for their students, and say, "thus far shalt thou go, and no farther?" This is exceedingly idle. They cannot fetter the minds of their members. As they learn the prescribed circle of studies, their minds will expand, and they will desire to learn more. More they will learn, and fancy themselves competent to the cure of any disease which may be presented for their opinion. Nay, more, it is the genius of every modern institution, as it is of the individual mind, to extend and elevate its scientific character. The Medical Profession have no guarantee that the Pharmaceutical Society, in following out its principles, will not seek to educate their members yet higher—to communicate some knowledge of anatomy, both healthy and morbid, and of the symptoms of disease, in order to prevent those serious accidents that may arise from ignorant counter-practice. The legality of counter-practice being once established (and we are sure that the Pharmaceutical Society cannot, and will not, attempt to interdict it), then a medical education is an absolute necessity. The Pharmaceutical Society would advocate it on a principle of common sense and public justice; and where is the defence for the General Practitioner? The Council of this Society profess to place a ban upon counter-practice; but it is a mere profession. Mr. Jacob Bell or Mr. Morson may denounce it, and be earnest in their denunciations, but they are not the whole body of chemists and druggists. It is *for their* interest to abandon counter-practice; but it is the interest of nine-tenths of their brethren to do directly the reverse, and it would be mere childishness—mere senility—to profess to legislate for any class contrary to the interests of that class. These professions are very silly. We have to deal with realities—with stern, unyielding facts—and it is our duty to estimate them at their true value.

In the low neighbourhoods of large towns, and in the provinces, the most profitable practice of the druggist—that, in fact, by which he pays his rent and taxes, and feeds his family—is counter-practice—an illegitimate encroachment on the duties of the General Practitioner.

Unsatisfied with a single administration for a sudden emergency, he continues, day by day, to prescribe his poisons, until death or disgust deprives him of his patient. The Pharmaceutical Society may profess to discountenance these proceedings, but they have studied but ill the genius and usages of their brethren, if they imagine that they can be successful in their legislation, by resorting to measures that shall cut off the economical resources of the majority of their order. They know better; they do not intend to do so; they will enclose all within their fold who will consent to join them, and then they will make the best bargain they can with the Parliament and the Profession.

For people to profess to commence legislation with restrictions upon their own members, is a mere hoax—a political chicane—which is employed merely to secure a more favourable consideration

of their plans. If they begun their labours with such an amiable simplicity of heart, we apprehend that the rapid defection of their members has taught them the folly of such a chivalrous Quixotism of conduct. Bye-laws and codes of honour have ever been inoperative for good. What they, however, cannot do, it is possible that some other body might; and since it is apparent that a restrictive power must reside somewhere, it is full time for the parties whose interests are engaged to determine where this power should be placed.

This question naturally leads us to the issue:—as to the propriety of legislating for the druggist prior to legislation for the General Practitioner of medicine. In the name of the General Practitioners of the country we protest against such an attempt. We declare that such a procedure will be the harbinger—nay, the accomplishment—of a fraud upon the General Practitioners. The Licentiates of the Society of Apothecaries are the only legal dispensers and sellers of drugs; the grocers, under the name of druggists, have usurped their functions, and now daringly attempt to legalise the crime. They should, at least, consult the wishes and seek the sanction of the parties they have injured before they set the seal upon this act of usurpation. Mere decency would have required so much courtesy at their hands. With a sophistry and hardihood becoming the original fraud, they say to the General Practitioner, "Do not interfere with us, and we will not interfere with you; let us enjoy our rights, and we will not molest yours!"

What, indeed, are the rights of the druggist? Have they not obtained all they possess by poaching upon the province of the General Practitioner? Fraud is their privilege. But stay: if a medical man, in the legal prosecution of his inalienable and immemorial right, sell a dose of medicine, he is charged by these persons with interfering with *their rights!* We want a word sufficiently courteous, yet sufficiently strong, whereby to designate this conduct.

Thus much, then, for the actual rights and legal position of the two parties. If the druggists think that we have stated the case too boldly, they must, at least, allow that it is perfectly true. Let us, however, take things as they are. We will admit the usurpation; we will suffer them to pursue the trade they have engaged in; we will abandon to them this portion of our duties; we will recognise them as a part of the established order of things, which we have neither the power nor the will to set aside. The trade in drugs is, then, their especial duty; and beyond this they ought not, in law, to be allowed to pass. Reserving to ourselves the practice of medicine, we forbid any further encroachment upon our duties. The druggists may claim to themselves the *citizen's right* of prescribing for any individual who is witless enough to ask them to do so, but we deny, in toto, that they should possess this right as a profession. A profession should be invested, in law, with certain definite powers and functions, or there is no use whatever in erecting a body of men into a profession by law. This is the nature of the thing. Moreover, when a man becomes a member of society he is obliged to relinquish many of his natural rights in order to promote the general good; and thus when a man enters a profession, he expects to enjoy certain special benefits, for which he consents to sacrifice some of these so-called citizen's rights. This is the common sense of the matter: if it be not so, abolish all professions, for they are equally useless and irrational.

We deny, however, this abstract *citizen's right*, on which the druggists rely, so much, for their justification. No man has a right to hazard the life of another; although he may have a citizen's right to do what he pleases with his own. The druggists have no right in statics, ethics, or religion, to do anything that may endanger the health or cause the death of another individual. Ignorance is not a crime in itself, but it is a crime to act in wilful ignorance. The amount of knowledge required for any specific act in which the life of another is implicated, may be conventional; but the state should require this amount to be obtained. This amount is determined by the aggregate knowledge of the learned, and by the condition of science, and the state which is the representative embodiment of this social wisdom, should require, in the due exercise of its chief function, the security of individuals, that this conventional amount of knowledge should be possessed by all men who are desirous to take upon themselves the responsible duties which ought not to be exercised without due sanction or delegation from the state. This is, in fact, the theory of professions. No man can have a citizen's right, who does not subscribe himself a citizen; to be a citizen a man must sacrifice many of his natural rights. And we declare that in the case before us, the druggist has no such citizen's right as he avers.

Seeing, in short, that the claims of the druggists to any part of the practice of medicine are indefensible, and that their indirect counter-practice can only exist by toleration and indulgence, we require at the hands of the State a restriction upon such unlawful practices. This restriction may reside either in the hands of the Government or in a council of our own. This is of little consequence, provided it be simple, efficacious, and of prompt application.

Again, we protest against legislation for the druggists in anticipation of medical legislation; for we know not how much trickery may be employed in Parliament to pass a measure detrimental to our rights and interests. We have the first claim, and when our position and privileges are established, we will cordially assist the druggists in obtaining a legislative enactment for themselves. Their object, in the main, is a laudable one, and we only request of them to make no attempt *"to remove their neighbour's landmark."* We are prepared to support any plan that shall define the position, determine the rights, and increase the respectability and usefulness of the chemists and druggists. Further we go not.

———Notandi sunt tibi mores.—HORACE.

WE last week adverted, in general terms, to the annoyances which medical men are in the habit of receiving from a certain class of mendicants, and itinerant salesmen. But there is another set of adventurers still more formidable, who come with a sort of *a priori* claim to one's regard, and are seldom unsuccessful in their appeal to one's benevolence. The class we allude to, are those who affect to belong to the profession, and to have been once better circumstanced than at present we find them. There is an uncommon irresistibleness in an attack like this, and right well must a man be on his guard to prevent it assailing the very depths of his pocket. We are by nature charitable, there is no doubt of it; and by custom rendered still more so, there is no doubt of that—and as few men are farther-sighted than they need be, it is no wonder, that most men should be, in some sort, liable to deception. Mendicancy, all the world over, is more a system of voluntary imposture than of necessity—everybody knows it is, and yet, scarcely anybody fails to commiserate the starveling of the street, even though it be doubtful whether he deserve one touch of pity. The fact is, amongst the many weak sides of human nature, one of the weakest is compassion; because it rarely pauses to consider the merit of the objects upon which it expends itself. This compassion, manifesting itself in indiscriminate benevolence, is one of the unavoidable consequences of *sympathy;* which we are inclined to regard as belonging rather to our physiological, than to our pyschological constitution. It is for the most part a very instructive sort of affair, for perhaps in nine cases out of ten, the man who carelessly drops a penny into a beggar's hat, does so with about as much thought and meaning, as he would resign himself to a fit of gaping, if he saw the beggar in the act of enjoying the same luxury. Does he yawn out of a love of imitating the grimace of a man he never saw in his life before? No, he yawns because he cannot help it, and it may even be, that the act is committed with some suspicion of a sacrifice of self-propriety. But so it is, instinct wars with volition, and gains the mastery of it. There is very much of this in alms-giving—the act has often neither meaning nor measure in it. Dealers in promiscuous charity, if they considered well the *cause* of their benevolent promptings and performances, would frequently find it akin to that natural weakness, which suggests a sigh and a tear, at the sight of a tragedy, which we know to be nothing more than "murder in jest." But it is due to the discretionary part of our nature to limit these vagaries of sympathy, and relieve the judgment of a charge of deliberating blindfolded. Indiscriminate kindness generally carries a curse with it; for it rarely fails, in some wise, to light on those who not only do not deserve, but are pretty sure to make corrupt use of it. Besides that it unworthily supplies the vicious with incentives to wickedness, it withholds from the virtuous the recompense that is due to them.

We offer this preface, as being, in our opinion, a not unfitting preliminary to a consideration of casual medical charity.

One of the most pitiable of living pictures is a fellow-creature, either alone, or with dependents upon him, degraded in spite of himself, and by an incontrollable fortuity reduced from worldly respectability to destitution! Over a sight such as this, sorrow and sympathy may utter their condolence in all the latitude of unfettered feeling! It is not a subject needing any imagination to pourtray, or any eloquence to appeal for it—its reality may be seen any day in our profession—and it pleads its own sufferings with a pathos sincere and irresistible. Such a case is one which ought to insure our cordial commiseration, and the best services of our bounty. It is an obligation we owe to the finer feelings of our common nature, to give them the opportunity of exercise, when an occasion like this falls in the way of their duty. Our instinctive faculties would prompt us so to do, and the more refined our intellectual and moral constitution, the more readily would it acquiesce in the suggestions of feeling.

The difficulty, however, is not so much to find sympathy for suffering humanity, as to find humanity that we are sure deserves sympathising with. There is no lack of the latter, we grieve to say; but it sometimes requires a very nice discrimination to distinguish between this, and the grosser variety that affects its resemblance. Hence, the temptation to deceit, and hence, also, the success with which deception is practised.

Upon no class of men is it practised more unsparingly, or more profitably, than upon the members of our profession, and for the very reason we gave in our last article—viz., because they are accessible to all comers, and few come appealing to their beneficence without departing well-satisfied with its efficacy.

One of the commonest tricks adventured upon us, is for a mendicant to present himself with the usual formality of a specious bow, and it may be, an unaffected offer of his hand, at the same time giving us to understand that he is a medical man who has called upon private business. This, of course, turns out to be, the communication that he is not quite so well off as he could wish to be and would gladly avail himself of the temporary accommodation of any trifle that can be conveniently spared. An ordinary beggar you can easily dispose of, if you have any doubt of him; and if not, he will free you from his presence if you give him a penny. But you cannot so readily dispose of a man "who has seen better days," and therefore, has a direct claim upon your good nature or, who, being a member of your own profession, can shake your hand with the frankness of fraternity. A man of this sort staggers you at once, and draws upon your bountifulness before you have a chance of stopping him. If it happen that he deserve all the liberality he receives, no fault can lie in the matter—and though your pocket should be emptied in the interview, there is little likelihood that you will sleep the less, or sigh the more, for having contributed largely to save an unhappy fellow creature from ruin. But if the reverse happen, the reflection is far from agreeable, that you have aided the adventures of a rascal and committed yourself unsparingly to his ridicule It must be remembered that rogues always laugh at those over whom their duplicity triumphs Unfortunately, however, we have no sleight-of-hand, no talismanic touch, no sign, manual or mental, nothing, in fact, to tell who are really of our fraternity, or not. Manner and method are a regular letter of recommendation to us, and though they may often deserve to be of the Bellerophon order, we have seldom enough of discernment or discretion to make them so. They dupe us, and it is our own fault that we deserve it.

We have often been placed in the difficulty we speak of, and have felt how hard a task it is to get out of it with justice, and at the same time without any sacrifice of generosity. Many a man has bowed us into a return of the compliment, and talked us into a charity we had better have avoided, whilst we have all the time had a doubt of him, and yet have been utterly unable to say so, or to proceed in anything like a systematic way to prove him an impostor. Some men have the happy facility of wheedling you out of your charity with such grace and readiness, that you are not sensible of your loss until it is too late to redeem it. Sheridan, as everybody knows, was one of this facile sort; and one of his greatest money-lenders used to vow his dread of asking the return of the principal, lest, in doing so, his debtor should borrow some more. There are plenty of small Sheridans to perpetuate the fame of the original; and though less dexterous, they may not be less dangerous, than their great originator. We speak from experience, for we have often suffered from their visitations, and are therefore not unprepared to warn others against their aggressions, or to caution them how best to prove their authenticity or imposition.

To deny, or even to doubt, *sans ceremonie*, the statement of a man who decently appeals to your favour, is to perform an not very inconsistent with the motives and manners of a gentleman. For this reason, therefore, it is no easy matter to give flatly, a denial to a mendicant who may come to you, affirming that he is a doctor out of place. At least his word is as good as yours, in the ordinary acceptation; and, in this case, it ought to be much better, seeing that he has had many more opportunities of becoming acquainted with his own station, than you have had of even learning the outline of it.

This is a difficulty we have encountered full often, and have found only one way of overcoming it. Our plan is, when a candidate for charity comes before us, prefacing his claims to commiseration on the ground of being, or rather having been, a medical practitioner, to say we have no reason whatever to doubt his word, and have therefore, no hesitation whatever in asking him a few professional questions. If he be a man of such decent exterior as to require that he be treated with some professional or conventional politeness, we commence the investigation by a discourse upon medical practice in general, and by degrees getting into particulars, so as to arrive at a pretty clear knowledge of his acquirements. The adventurer soon shrinks from this method of searching him, and suspecting the purport of it will feign illness, engagement, anything, rather than risk the scrutiny. He generally finds a sudden occasion for departure, and never fails to forget the immediate object of his visit. He has cunning enough to know that it is useless to ask for charity from a source already suspicious that he does not deserve it. It is needless to say that the reverse character rather courts conversation than shuns it—anxious to show what his merits are, and how poorly they have been requited.

There is a less formidable (fashionable, we mean) class of *soi disant* professional applicants for one's bounty, whom we are accustomed to dispose of summarily, with or without relief, as the case may appear on scrutiny. To such applicants we are in the habit of saying, we have no knowledge of you, or of the circumstances you represent, yet shall be happy to afford you some relief, provided you can give us proof of the sincerity of your statements. Singularly enough, they have invariably expressed their readiness to furnish every proof we wanted of their professional orthodoxy, and yet, in by far the majority of cases they have been utterly incompetent to the task they adventured. The tests we have employed, have been simple conversation concerning the present and past state of physic, or any of its relative sciences; a request that the applicant would give a translation of a passage in the book put before him (Celsus, Gregory, or the London Pharmacopœia); or give the name and description of some bone or anatomical specimen submitted to his scrutiny. In some of these cases we have met with extraordinary characters, who have drawn largely upon our mirth, compassion, or contempt. They are striking enough, however, to deserve that we shall give them consideration and comment in a subsequent article.

THE HOMICIDAL MANIA.

It is known that Mallard, the pawnbroker from whom Wix purchased the pistol with which he shot Bostock, his master, was the shopkeeper from whom Graham subsequently bought the pistol with which he shot the stranger, Blewitt. This fact, sufficiently striking of itself, is made more remarkable by the pawnbroker's evidence, which tends to prove that, what looks likes a mere coincidence was, in fact, but the operation of a moral law, and that where the appearance was an accident, the reality was a principle. "*Immediately*," says the pawnbroker, "*after the assassination by Wix, I received a great many applications for pistols, and now, within the last few days*," (after the second tragedy) "*several persons have applied to me for the same thing*. I am now determined, however, never to sell another." Passing by the very proper resolve adopted by this tradesman of mishaps, we find in the fact he records, a startling revelation of the mental condition of a portion of that public authors and orators are so fond of bepraising. To many of our London denizens there would appear to exist a fascination about the circumstance of murder. About us and near us, arrayed in all the externals of common sense and charity, are persons endued with a mesmeric sensitiveness to the horrors of homicide, from the very intensity of whose abhorrence of crime arises an interest for it, tempting and fascinating them to its commission. The spot—ensanguined by the tragedy—becomes to them a centre of attraction: it is hallowed ground. A pistol from the shop of the murderer's choice acquires additional value: for weeks and months after the catastrophe there are minds (of people at large, too) meditating and brooding over its exciting incidents, and a lust for imitation fastens on the morbid brain that wants nothing but a favourable opportunity to make crime irresistible. Graham, the youth of fifteen, has scarcely got possession of his pistol from the shop that supplied his murdering predecessor, when he kills with it one of the first persons approaching him, and this, too, in the very scene of the former tragedy. The associations of the deed and place were too powerful for him. So placed, the smallest circumstance sufficed to enkindle and educe the latent mania. The mere jostling in the street against a female—a stranger to him—excited the morbid propensity beyond control. By some caprice or accident she and the next comer—a journeyman printer—though threatened, escaped —the third fell. So strange—so sudden—so undistinguishing was the homicidal *fit*.

Forgetting for a moment a general question that here uprises, let us say a word or two on the extent of the boy's moral and legal responsibility. The moral guilt will depend on his intentions, knowledge, and freedom of action. These, separately or conjointly, form the elements of all human merit or guilt, and under either of these, we fancy, in this case it would be difficult to attach a heavy culpability—if any. There was, undoubtedly, a raving—*an intention*, if you will—to destroy, but it is far from clear that the *intention* directed itself to *human* life, in especial, and it is quite certain that it did not to any particular individual. The essence of intention was, in fact, wanting. *Materially* there *was*—*substantially* there was *not*—an intention. A brute instinct was in operation, not the volition of a reasoning entity. On the question of *knowledge* the case is still stronger. To act with knowledge almost necessarily presupposes a motive, and enforces some little attention to consequence. Here there was none. There was no hate, and no cause of any; no hope of advantage, and no chance of any. No wish for escape; no expression of regret or joy when the act had been perpetrated. In fact, a knowledge of what he was doing—all motive being absent—presupposes the existence of an organic cerebral disease, making him the victim of an irresistible compulsion. To know what he was doing—as the case

stands before us—and still to have done it, would have been to labour under an insanity of the very worst kind; the ordinary principles of human action could have had no more influence on him than on the most excited inmate of Bedlam. So that, under any hypothesis, the inference is all but resistless, that in the act before us there was a want of intention—of knowledge—or of freedom: or it may be of all three: a want which, as far as our judgment can see, does relieve, and should relieve, the agent of the heavy burden of moral responsibility.

Connecting with these general considerations the peculiarities of the boy's character and person, great force is added to our inference. His dress was peculiar—his look "sallow and bilious." There was in his mental constitution an inexpilicable love of fire-arms. Shooting was a passion with him. His room was a shooting-gallery; he collected around him books on shooting; he was proceeding to take lessons in shooting when the humour of killing somebody took possession of his mind. There, seems, in fact to be a diseased organism in the boy, which, *à priori*, admonishes us that without any actual viciousness he would be capable of acts the most irrational and outrageous, on impulses the most sudden and bizarre, or on external excitations the most trifling and singular. We are not of those, however, who would identify necessarily *moral* with *legal* responsibility. In ethics, we condemn in relation to the actual departure from some admitted standard of right: in law, we punish in relation to the effect which penalties have on society. Thus, law may at times justly be severe, where the moralist is as justly lenient; and the moralist be rigorous where the law is lax. We grant, therefore, that the jurisprudence of our country may, not unwisely, look with a jealous eye on the attempts made to palliate by novel pleas of an equivocal species of insanity, breaches of her ordinance. The insanity so mischievous might be encouraged and increased by the example of impunity, as it might be checked and cowed by the evidence of striking retribution; and the rightful defence granted to one afflicted mind might be made the cunning shelter and cover of a hundred calculating villains. But while admitting that the sanctions of law adapt themselves more to the exigencies of society than to any abstract proportion to the code of moral wrong, it still behoves us to say that the latter idea must not be recklessly violated in legislation if we mean to purvey to the social well being; and that to doom a person in the pschycological position of this youth to the disgraceful end that was supposed to be in measure to the decisive criminality of a Corder and a Greenacre, would be a revolting instance of cruelty and startling injustice, that would not only throw discredit on all jurisprudence, but make it fail in the very end of its being. Such things shock justice and disorganise the social system.

We have left ourselves little space for observation on the general question to which we adverted, viz., the existence of a form of moral mania in many persons moving at large in society, whose morbid instincts or propensities, varying often in their tendencies, are roused into ungovernable action by excitations derived from the excitement of notoriety, or the fascinations of example. There is no mental delusion; the intellect is much as usual; there is the customary sense of right and wrong, though unused and unthought of in the excitement, that holds possession of the whole person. All that is at fault is some perverted feeling. A natural passion, from some form of physical disease existing in the brain, acquires an unusual and complete predominance, and succeeds either in setting the intellectual faculties at defiance, or making them subsidiary to its violent impulses. If the diseased propensity be that which refers to the acquisition of property, we have theft under all circumstances; so that persons have been known who would not eat their food unless they had first stolen it. It is thus also with enormous madness, suicidal monomania, and incendiarism; but it is in homicidal mania that we look for the most striking illustrations of this mysterious form of cerebral disease. The instances on record of the dreadful exercise of this perverted instinct, under circumstances the most peculiar and afflicting, are numerous and well-authenticated, and the law is now well established among cerebral physiologists, that to persons thus diseased the latent impulse—the lurking demon—is often forced into resistless action by the influence of a striking or notorious example. One startling and celebrated murder is the sure herald of several. The notoriety attracts to a congenial crime the diseased minds of thousands; a morbid sympathy is created; there is fascination in the gulph; the diseased propensity is stimulated, excited, and made to overwhelm both volition and reason. The last agency wanted is supplied to make the madness culminate.

In this fact, or rather law, there is much that may be pondered over with scientific advantage by the physiologist, but to the makers and administrators of our country's jurisprudence it is of an importance not to be exaggerated. In the conduct of public inquiries in the execution of the last ordinances of the law, there is a parade of "*spectacle*" and dramatic effect which might be avoided with advantage, if we would not seek to cultivate the morbid or depraved tendencies of our population; and in the application of the rules of justice to offenders it might not be amiss if our judges were to attach themselves less to the cold, ignorant, and prejudiced dicta of old legal authorities, and pay more homage to the well-rounded discoveries of an advanced and rapidly improving science. It is certainly no honour to the humanity of England, and no distinction to the discrimination of her judges, that she has ever and anon—even in these days of physiological advance—a maniac dangling on her scaffold as a criminal.

MISCELLANEOUS CORRESPONDENCE.*

HICKMAN *versus* DICKENSON.

[To the Editor of the Medical Times.]

The charge of the judge to the jury, in the case of Hickman *versus* Dickenson, lately reported in your spirited journal, was manifestly wrong; as not borne out by the evidence which was elicited on that interesting and important trial.

What are the facts of this deplorable case? A young and previously healthy woman lay dying from uterine hæmorrhage, connected with, and kept up by, retention of the placenta, after delivery of her first child. A surgeon was sent for. He did not arrive until nearly two hours had elapsed from the reception of the summons.[1] The gentleman appears to have been well aware, as all enlightened practitioners in obstetrics must be aware that the hæmorrhage would not subside until the placenta had been removed, and the orifices of the bleeding vessels in the uterus had been allowed to close by the consequent contraction of the organ. Under this impression, Mr. Dickenson introduced his *hand* into the vagina, although in no very determined or workman-like manner; and withdrew what he believed to be the placenta, and subsequently shewed to Mr. Best, on his arrival, as such. Mr. Best, however, with his natural acuteness of observation, at once discovered that the supposed placenta consisted merely of some coagula of blood and skin,—probably a portion of the membranes of the ovum; and proceeded, with his characteristic decision and intrepidity, to extract the placenta, as the only chance of saving the woman's life.

The proceeding of Mr. Dickenson proves, beyond all doubt, that he was clearly acquainted with the modern practice in such cases, and understood his duty. But that he should have lacked presence of mind and courage to perform it effectively, and that he, a regularly-educated and experienced practitioner, should have mistaken a clot of blood for the placenta, are circumstances explicable only upon one hypothesis; which, in my present state of ignorance as to its correctness, I should deem it alike ungenerous and impolitic to advance.

Had Mr. Dickenson expressed to the attendants of the unfortunate woman, his opinion as to the inexpediency, or danger, of making any attempt to remove the placenta, in her exhausted condition; and had he, in conformity with such opinion, abstained from all efforts for its removal, then might the judge, with some colour of truth and consistency, have interposed his plea of diversity of obstetric practice, built upon an exploded opinion of the late Dr. Denman, in behalf of the defendant; and, peradventure, been justified in his rude attack upon the character and feelings of Mr. Best. But how the judge could have advanced such an argument in justification of Mr. Dickenson, and *in direct opposition to the practice which the defendant had, himself, unsuccessfully because inefficiently, pursued*, I am utterly at a loss to comprehend.

Upon the elders of my profession I presume not to obtrude unsolicited counsel. But should any one of my younger brethren, in general practice, meet with such a case as that upon which I am now commenting, I earnestly exhort him, after the administration of a suitable stimulant, and the application of cold, with pressure, to the abdomen, to set to work with a *bare arm* and cool, yet determined spirit: and, in nine cases out of ten, he will have the unspeakable gratification of rescuing his patient, in the hour of her extremest anxiety and peril, from otherwise inevitable death.

Nor let him be discouraged from the stern and unflinching prosecution of the path of duty, which his judgment indicates and sanctions, by a retrospect of the sorry treatment experienced, in the present instance, by Mr. Best. In cases of professional failure, or mishap, the odium frequently falls upon those who have least deserved it. Yet there are in the fearless performance of our duty as professional men, however unsuccessfully the case may terminate, a conscious pride, and a consolation which he, who basely flinches in the hour of peril, can never feel, and of which the world's opinion cannot deprive us. And professional talent and intrepidity, like virtue, however obscured for awhile by obloquy or prejudice, will ultimately meet with their full reward.

In the present communication, I have had no object in view but the honour and the interests of the beneficent profession to the study and practice of which my life has been devoted. With Mr. Dickenson I am utterly unacquainted. Mr. Best I know something of: and, like all others who have that pleasure, I know him only to respect his character and his talents.

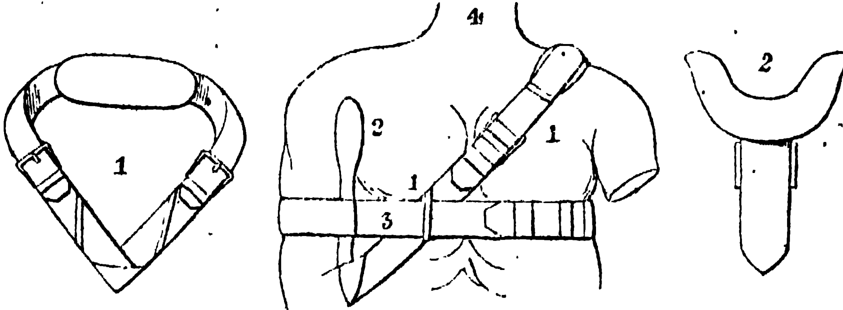
I remain, Sir,
Most obediently, yours,
MEDICO-CHIRURGUS.

Birmingham, April 24, 1846.

[1] "He (Mr. Dickenson) was sent for at a quarter after twelve; but did not arrive till nearly two." Evidence of Hannah Tudor; as given in the report of the trial, by the *Birmingham Journal*, for Saturday, March 28th, 1846.

APPARATUS FOR THE TREATMENT OF CERTAIN INJURIES OF THE SHOULDER.

(To the Editor of the Medical Times.)



SIR,—I beg you will do me the favour to insert in one of your early numbers, a copy of the annexed diagram, and description of a simple apparatus invented by me, for the treatment of certain injuries of the shoulder. wherein it is necessary to

raise and support the arm, but, more particularly fractures of the clavicle. Having witnessed in many cases of this latter injury, the annoyance and irritation produced by the common way of treating it, by the figure of 8 bandage, as well as by the more complicated method of Desault, and other more modern contrivances, I was induced to attempt something to remedy their inconvenience, and having succeeded effectually, I now venture through your widely circulating journal to introduce the same to the notice of the profession.

I am, Sir,
Your most obedient servant,
J. Ellis, R.N., M.R.C.S.E.

MR. SETON'S CASE.

To the Editor of the Medical Times.

Sir,—The greater part of the *seance* at the meeting of the Medical and Chirurgical Society having been occupied by the reading of Mr. Liston's paper, and so little time having been left for discussing the important question submitted to the fellows for consideration, I did not think that the debate was to be finally closed, so as to prevent any further remarks at a subsequent meeting, and supposing the question would be again brought forward, I attended last evening, intending to make one or two additional observations in reply to those of Mr. Liston; and after the thanks of the Society had been expressed to the author of an interesting paper which was read, as no one seemed disposed to comment upon it, I reverted to the subject of discussion of the former meeting, but desisted upon the intimation of the president that more time must be allowed to see whether any remarks would be offered upon the paper which had been read. A silence of several minutes still continuing, the president proposed to pass on to the reading of another paper, when a gentleman, at length, rose to speak, who was followed by two or three others. In the meantime a member stated to me his opinion, that it was contrary to the rules of the Society to revert to the subject of a former discussion, which the president, after referring to the rules, confirmed. Being but little of a debater, I had attended but few of the meetings, but was induced to go and hear the discussion upon a case which had attracted so large a share of public attention, though not expecting to take any part in it myself, and I was somewhat surprised at the long silence that followed the reading of the paper, as I had heard that some members, who objected to the treatment, would be present; and Mr. Liston afterwards stated that he had written to several gentlemen, who he understood had criticised his practice very freely, but for some reason or other they had declined to attend. Did it not strike Mr. Liston that persons, with whom he was on terms of intimacy or acquiutanceship, might not perhaps like publicly to express their disapprobation of his practice? But, at all events, the absence of members whose position would authorise them in freely expressing an adverse opinion, could scarcely be construed into a general approval by the profession of the treatment pursued; and I was induced to submit the few observations which I made to the Society, not with the intention of imputing blame, which (not having seen the case) I should not have felt myself justified in doing, but in order that the principle which the consideration of the question involved, viz., that of tying the proximal portion of an artery of the first order, in a case of traumatic aneurism, which had existed a few days, and which, I conceived, was opposed to that laid down by the first authorities, should not go forth under the sanction of Mr. Liston's name, and those of one or two other gentlemen whose opinions have weight with the profession, and stamped with the approbation of the first medical society in the kingdom without some reference to the exceptional conditions demanding consideration, especially when the external iliac is implicated, and thus constitute a precedent for encouraging the tendency to operate, which it is the peculiar characteristic of British surgery to avoid as much as possible.

Mr. Liston observed that he "could not understand the gist of my remarks, which did not appear to him to have any direct bearing upon the case;" but I think the fellows of the Society, and those who have read the report of the debate, will consider that they did bear most directly and solely upon the practical part of the question; their purport being to object to the principle of applying a ligature to an artery, by which the supply of blood would be suddenly cut off from nearly one-fourth portion of the body, without there being any adequate means of supplying the deficiency; and this objection would, more particularly, apply to a person accustomed to free living, of a full habit of body, who was already exhausted by loss of blood, and in whom there was no recurrence of the hemorrhage, although there might be reason to apprehend such an event, which even had it occurred, would not have been necessarily irremedial without having recourse to so extreme a measure, even if the crural itself had been certainly wounded; and I think the opinions which I expressed in the Society will be found to be corroborated by the best authorities, upon similiar questions, of whom, perhaps, there is none higher than Larrey, who observes, in his *Clinique Chirurgicale*, with reference to traumatic aneurisms—"The ligature is truly the most sure and certain remedy, but only when it is applied to vessels which are removed from the principal arterial trunks. In arteries of a secondary order, where the anastomoses are more numerous and stronger, the ligature may be applied with much greater chance of success, and thus secure in a prompt and certain manner the existence of the patient and the preservation of the limb; but, on the contrary, in cases where the chief arteries, as the common carotid, subclavian, axillary, external iliac, or crural, are injured, the same rule would not apply; the ligature is not always practicable, and whatever may be the opinions of authors, it has not always the success hoped for."

This, be it observed, has reference to the cases where the principal trunks are wounded, and if it be just as regards the carotid, axillary, and crural, where there are more abundant means of carrying on the collateral circulation, how much more must not the same observation hold good in the instance of the external iliac, which gives off no branch above the epigastric, and supplies so large a portion of the body with blood.

"The anastomoses of the arterial branches, from the portion of the artery above the aneurismal tumour, with those arising below it, become less developed in proportion as the tumour is formed rapidly or suddenly, and the success of the operation is less to counted upon than when the tumour is formed slowly. It is then, doubtless, preferable, especially when the great arterial trunks are implicated, to amputate the limb. Sedatives should, however, be previously tried, and their use persisted in.

"In order to corroborate our opinion respecting the uselessness and the danger of tying the chief arterial conduits, we will relate the following cases:—

[Here follow several illustrative cases.]

"Now, if we compare the operation of tying the principal trunks with our sedative and revulsive method, we shall see, on the one hand, an operation more or less difficult of performance as regards the surgeon, and as regards the patient very painful, and of so uncertain a result, that of thirty individuals, where the subclavian, the origin of the axillary, the external iliac, or the origin of the crural arteries were tied, there are scarcely four or five cases in which the success is complete. Our method, having none of the inconveniences of the ligature, presents, on the contrary, the advantage of arresting the progress of the evil, of favouring the formation and development of new arteries, obliterating the trunks of the wounded ones by provoking adhesive inflammation in the coats of these arteries and of the surrounding parts. The effects of ice seem to us to be extended to all parts of the circulation; the arterial and venous systems becoming constricted in their diameter, and all the internal organs necessarily experience the influence of the process of constriction or atrophy.

As we have already said, when traumatic aneurisms are connected with arteries of a secondary order, as the humeral, radial, femoral, popliteal, or their branches, the ligature may be preferable to any other means, especially if the patient desires the operation, because mortification of the limb is not to be feared, and because it would be useless to subject the patient to a state of absolute repose, a rigid diet, and the application of ice, during the time requisite for the obliteration of the vessels which are the seat of the aneurism, and for the production of those which must replace them, which regimen many patients would but ill bear."

More might be said upon the question, but I fear that this letter will already take up a great deal of space in your columns.

I am Sir,
Your obedient servant,
Edwin Lee.

13, Curzon-street, April 29, 1846.

[We regret this letter should have been omitted from our last number; its omission was unintentional.—Ed.]

THE LATE MR. JOHN SCOTT.

Mr. John Scott was born in 1798, and was the only son of Mr. Scott, of Bromley, a gentleman well-known, and deservedly respected, as one of the most successful general practitioners of his day.

In the extensive field afforded by his father's practice, Mr. John Scott early imbibed a taste for the surgical branch of our profession, and probably, also, in the same school, he gained that confidence in the resources of his art, which, in after years, characterised him as a practical surgeon.

The commencement of Mr. John Scott's education was conducted at a private school, at Sevenoaks, whence he was sent to the Charter-house, where he displayed much of the spirit and energy which marked his subsequent career; and upon leaving that establishment, he was apprenticed to the late Sir Wm. Blizard, then the senior surgeon to the London Hospital.

Every advantage, which a youthful seeker after professional information could require, was now open to him, and most eagerly did he use his opportunities for gaining knowledge.

After obtaining the diplomas of the Royal College of Surgeons and the Apothecaries' Company, Mr. John Scott settled at Bromley, to share his father's lucrative practice, and he very shortly after formed

a matrimonial alliance with Miss St. John, the daughter of a church dignitary of that name.

Though most men would have esteemed themselves fortunate in possessing a part of so large practice as that of Mr. Scott, of Bromley, the restless, energetic, and ambitious mind of Mr. John Scott could only find a suitable expanse for it exercise in our great metropolis, and he accordingly soon after took up his residence in New Broad-street. Here his practice increased to a considerable amount, with a rapidity perhaps unequalled by that of any other consulting surgeon of his age. The profession, ever jealous of great success, attributed Mr. John Scott's progress entirely to the *prestige* of his father's name, while on the other hand, himself with little candour ascribed it exclusively to his own merits and energy. The truth may be found between the two extremes—his father's name procured him many excellent patients, and his high professional qualifications—his untiring zeal, and scientific and dexterous application of his father's mode of treating ulcers and diseased joints, grafted as it was upon a sound professional education, enabled him to surpass his father even on his own ground, and to take a high position both with the profession and the public.

Soon after he came to London, Mr. Scott was engaged in two very active canvasses—one for the office of assistant-surgeon to the London Hospital, and the other for an appointment to the Ophthalmic Hospital in Moorfields; in the former, though defeated by a long previous canvass on the part of his opponent in the first instance, on a second vacancy occurring soon after, he was elected without opposition; in the latter, after a very fierce contest with a senior candidate, possessing very powerful city interest, he gained the day—his triumph being on this occasion due partly to his great activity, and partly to the opinion held by the governors that he was the more talented and useful man of the two; he was also soon after this appointed lecturer surgery at the Medical School of the London Hospital.

We now see Mr. John Scott possessed of all that a young aspirant for fame and fortune could desire, attached to two of the largest hospitals in London, a public teacher, and in the enjoyment of a lucrative and rapidly increasing practice. As years rolled on, many of his most ambitious hopes were realised; he for some time possessed the largest city practice in London; he performed some of the most formidable operations in surgery with success, and obtained a high reputation as a bold and successful surgeon; but, when yet in the prime of manhood, insidious disease commenced its ravages, and though he struggled hard against it for some years, at length prevailed, when yet only in his forty-eighth year. He clung to his several appointments with a remarkable tenacity, and performed their labours, when disease and weakness rendered such efforts painful to himself and others, and only resigned them one by one, when his prolonged absence from their duties rendered his resignation almost imperative.

We shall now proceed to take a brief survey of Mr. John Scott's character as a surgeon, a teacher, an author, and a man.

As a surgeon he was distinguished by remarkable rapidity in diagnosis, and much decision and energy in treatment; having once formed an opinion, he never wavered in the plan to be pursued or allowed his feelings for the patient to modify in the least degree the severest treatment his judgment dictated. A case seldom lingered under his hands; though it must be owned that, when he failed to ameliorate, he often aggravated the condition of his patient. As an operator he was bold but not cool, and rapid without being dexterous He aimed too much at a "*coup de main*," and sometimes used force when manœuvre would have succeeded. He was, we believe, the first in England to perform the bold operation of removing the superior maxillary bone for disease of the antrum, this he did successfully, though discouraged by his senior colleagues. As a public lecturer he was verbose, and had much mannerism. As a clinical instructor he was far more successful; and he commented with much clearness and spirit upon his cases, and explained very graphically the principles upon which he acted. He was the first to set forth and exhibit to the profession, both theoretically and practically, the immense advantage to be derived from mechanical support in every variety of chronic disease; and he was the best applier of strapping and bandaging in England, both as regards rapidity and perfect adaptation of the amount of pressure suitable for the particular case —a skill which is only to be acquired by long experience and careful observation; for his exposition of this, the profession owe him a deep debt of gratitude, which they will be the more willing to pay as they learn experimentally the value of the plan he was the first publicly to inculcate, both in his work on the Diseases of the Joints and in his lectures. As an author he could not, however, expect to be very successful, being neither an extensive reader, a close reasoner, nor a deep thinker.

In his private character he was justly respected as a man of honour and strict integrity; but his uncertain and irritable temper, aggravated, perhaps, latterly by disease, rendered his manner to his patients, and even to his friends, repulsive and overbearing, though when he was pleased few could be more agreeable; he always seemed fond of children, and deeply regretted his having no family. With his colleagues he was always in a condition of antagonism, or of assumed superiority—there was no alternative between submission and opposition. His principal pleasure was derived from some triumph over another, regardless of wounded feelings. General practitioners rarely, if ever, called him in a second time. Enemies, as may be imagined, he had many; of private friends a very limited number, and from this it may be readily conceived that, notwithstanding his possession of every outward means of happiness, that subtle thing eluded his grasp; externally there was triumphant success, internally there was irritability, restlessness, and dissatisfaction. He had no sympathy with humanity, and consequently a fruitful source of h[illegible]ness was never open to him.

In person Mr. Scott was tall, thin, and active, and his sharp rigid features and quick grey eye were to an acute observer an exact index of the mind within.

Mr. John Scott has left a widow, a father, and a sister to mourn his loss; the latter is the mother of a large family

Report says that he has died rich, and, after leaving a jointure to his widow, has bequeathed the bulk of his property to charities, entirely omitting those by which he rose to affluence, and chiefly selecting those of an evangelical order.

GOSSIP OF THE WEEK.

Mr. Dermott.—Our readers have been apprised that this eminent and successful lecturer on anatomy and surgery (for a considerable time the pupil and assistant of Brookes) was excluded from the fellowship by his brother teachers occupying seats in the Council of the College of Surgeons. By an odd turn in affairs it has been the fate of this gentleman to complete the education of many of the surgeons who have since passed the college examination as fellows. His marvellous power of imparting in a short time practical scientific information has given "Fellows" to the college which declined to allow him the distinction he is thus the cause of to so many others.

Apothecaries' Hall.—Gentlemen admitted Licentiates on the 7th of May, 1846.—Richard Sandford, Edward Lowdell, George Johnston Langsford, John Rome, John Griffith Morris, William Burns Beatsan, William Frederick Cleveland.

Royal College of Surgeons.—The following Gentlemen were admitted Members of this College, on Friday, May 8th, 1846:—viz, Messrs. J. Ward, J. D. Blake, C. C. Hailey, F. Sibery, E. C. Thorp, D. Evans, R. R. Crucefix, N. J. Hobart, R. Allen, F. C. Jones, J. Syme, and J. S. Smith.

Mr. Field has been elected house-surgeon to the Royal Sea-bathing Infirmary, Margate.

His Majesty the King of the French has been pleased to confer the decoration of the Legion of Honour on Dr. Ollille, a distinction seldom granted to foreigners residing in France.

Charing-cross Hospital Medical School, West Strand, London.—The annual distribution of prizes and testimonials of honour to the students most distinguished for their acquirements in the various branches of medical study at this institution, took place on Wednesday the 6th of May, 1846, the Rev. G. H. Bowers, B.D., in the Chair. The following gentlemen were the successful competitors:—Chemistry: Silver medal, Mr. Thomas Sutton Ludlow, Hanworth; a book, Mr. George W. Paternoster, Lambeth. Materia Medica: Silver medal, Mr. George W. Paternoster; first honorary certificate, Mr. Robert Hamilton, Ipswich; second honorary certificate, Mr. F. W. A. Rawlins, London. Anatomy (Senior class): Silver medal, Mr. Henry Lambden, London; (Junior class) bronze medal, Mr. George W. Paternoster; certificate, Mr. Robt. Hamilton. Midwifery (Senior class): Silver medal, Mr. George B. Payne, Manchester; certificate, Mr. Henry Watts, London; (Junior class) bronze medal, Mr. Henry Lambden, London; certificate, Mr. C. R. Durell, Jersey. Physiology (Senior class): Silver medal, Mr. Henry Lambden; (Junior class) bronze medal, Mr. George M. Young, Bucks. Medicine (Senior class): Silver medal, Mr. Joseph Fayrer, Bermuda; certificate, Mr. John W. B. Steggall, London; (Junior class) bronze medal, Mr. C. R. Durell. Surgery (Senior class): Silver medal, Mr. Joseph Fayrer; a book, Mr. J. W. B. Steggall; (Junior class) bronze medal, Mr. C. R. Durell. Botany: Silver medal, Mr. C. R. Durell; certificate, Mr. Joseph Fayrer. Medical Jurisprudence: Silver medal, Mr. J. W. B. Steggall; a book, Mr. Joseph Fayrer. Governors' Clinical Prize: Silver medal, Mr. W. Cox, Wales. General Proficiency: The gold medal, Mr. Henry Watts, London. Diligence and good conduct (honorary testimonials): Mr. Jago; Mr. John Lynch, Shadwell; Mr. R. Westley, London; Mr. Stillman, Shropshire.

In consequence of the repeated attacks on the Dr. Moizin, member of the superior council of health, has been created knight-commander, and Drs. Long, Bravet, Chassinat, Hubert, Hutin, Cagnon, Briard, Jousserandot, Billardet, and Bernard, knights, of the legion of honour. Dr. Lutens, an army-surgeon, has been created a knight of the order of Leopold in Belgium. If an order of merit were created for civil services in Great Britain, many members of our profession would be found entitled to receive its honours. "They manage these things better in France."

Obituary.—Recently M. Mabit, sen., director of the school of medicine at Bourdeaux, and honorary physician of the Hôpital Saint André.

MORTALITY TABLE,

For the week ending May 9, 1846.

Causes of Death	Total.	Average of 5 summers	Average of 5 years
All Causes	811	892	968
Zymotic, or Epidemic, Endemic, and Contagious Diseases	130	162	188
Sporadic Diseases—			
Dropsy, Cancer, and other Diseases of uncertain or variable Seat	86	98	104
Diseases of the Brain, Spinal Marrow, Nerves, & Senses	142	155	157
Diseases of the Lungs, and of the other Organs of Respiration	279	271	294
Diseases of the Heart and Blood-vessels	27	26	27
Diseases of the Stomach, Liver, and other Organs of Digestion	72	65	72
Diseases of the Kidneys, &c.	11	7	7
Childbirth, Diseases of the Uterus, &c.	15	9	10
Rheumatism, Diseases of the Bones, Joints, &c.	18	6	7
Diseases of the Skin, Cellular Tissues, &c.	2	1	2
Old Age	39	60	67
Violence, Privation, Cold, and Intemperance	16	25	26

PROGRESS OF MEDICAL SCIENCE,

INCLUDING CHEMISTRY AND PHARMACY.

France.

[From our own Correspondent.]

ACADEMY OF SCIENCES.

Meeting of 11th May, 1846; M. ELIE DE BEAUMONT in the Chair.

DISTRIBUTION OF PRIZES.

Astronomy.—The prize (a gold medal, value £25) was divided between M. de Vico, director of the observatory of the Roman College, and M. Darrest, attached to the Observatory of Berlin. Each of these astronomers discovered a comet during the year 1814

Statistics.—M. Chalette, for his statistics of the Département de la Marne.

Experimental Physiology.—(gold medal, value £35)—M. Agassiz received the prize for his work on living and fossil fishes; another prize was awarded to M. Bishoff for his treatise of the development of the ovum and of the fœtus of the dog. M. Raciborski was also distinguished by the commission as having extended to the human race the researches of M. Pouchet relative to the spontaneous ovulation of mammiferæ.

Improvement of Insalubrious Arts (£80).—M. Chaussenot received this prize as a recompense for the invention of an apparatus destined to diminish the chances of explosion in steam-generators.

Medicine and Surgery.—The first prize (£60) was awarded to M Amussat for his researches on the wounds of the vascular system. This is the fifth prize awarded to the learned surgeon by the Institute, his researches on lithotrity, the torsion of arteries, the introduction of air into the veins, and lumbar enterotomy, having been all judged by the Academy deserving of recompense. M. Milne Edwards, the reporter of the commission, in proposing M. Amussat for the first prize, observed that, although many surgeons, both ancient and modern, had already turned their attention to the study of the difficult question of vascular lesions, M. Amussat found something more to glean in the field of observation, and had arrived at conclusions interesting, not only to physiology, but to operative surgery. His experiments have been chiefly performed upon sheep and oxen slaughtered according to the regulations of the Jewish religion, and permitted him to study with accuracy the local phenomena consequent upon complete section of arteries in a broad transversal wound. He has shown that hemorrhage is spontaneously arrested, not by contraction of the artery, but by the formation of a clot, forming at first, not a plug, as it has been asserted, but a ring, which becomes, by the deposition of fibrine, gradually narrower, until the orifice is entirely closed A second clot, independent of the first, forms within the vessel, and the hemorrhage is stopped. M. Amussat has given the signs by which the orifices of vessels, obliterated in a temporary manner by such clots, are to be recognised on the surface of a wound, in order that a ligature being placed on them, secondary hemorrhage may be prevented M. Amussat also gives most interesting details on the formation of hematic tumours under the skin, on the cicatrisation of veins and arteries, and on the production of traumatic aneurism.

A second prize (value £50) was granted to Dr. Bonnet, of Lyons, as a reward for his researches on diseased joints. The novelty of Dr Bonnet's views, and the method of experimental inquiry, which the author has followed, recommend, said the learned reporter, this work to the encouragement of the Academy. In order to ascertain the better certain mechanical effects of hydrarthrosis, M. Bonnet made experiments on the dead body by forcing injections into the articular cavities, and recognised with certainty the position which the limbs must acquire under the influence of this sort of dropsy, the new connections of the articular surfaces with each other, and the road followed by the extravasated liquids when the capsule is distended beyond the limits of its elasticity. The commission also noticed M. Bonnet's researches on articular fungus, and his remarks on the cure of hydrarthrosis by the iodine injection.

A prize of £25 was awarded to Drs. Becquerel and Rodier as an encouragement for their researches on the composition of the blood in health and in disease. To M. Réveillé Parise £20, for his remarks on the dressing of wounds with thin plates of lead; to M. Morel £20, for his memoir on dislocations of the clavicle, and to M. Clias the same sum, for his new method of gymnastics.

The meeting adjourned after the panegyric of the mathematician, G. Monge, was pronounced by M. Arago.

ACADEMY OF MEDICINE.

Meeting of May 12th, 1846; Dr. ROCHE in the Chair.

CASE OF PELLAGRA.—M. Honori read the case of a patient whom he supposed to be affected with pellagra M. Emery remarked that the symptoms assigned to that disease did not appear to have been present in the case related by M. Honori, which might more properly be attributed to softening of the spinal cord. When the case has been further investigated we will forward an account of it to the *Medical Times*.

DISEASES INCIDENTAL TO THE CLIMATE OF ALGERIA; BY C. BROUSSAIS, M.D.—Disease is more common in Algeria than in France; 50,000 men giving a yearly average of 60,000 patients, the same men being several times in the year admitted into hospital. The mortality is also greater, the army losing 8½ per cent. in a twelvemonth, and only 2½ per cent. in France. The mortality has, however, much decreased since the occupation, having fallen in 1843 to 6 per cent. In this respect the French colony enjoys an advantage over the British possessions, where the average of disease is equal to double the number of effective men; the mortality being equal to 10 per cent. February, March, and April are the most healthy months, in June epidemics begin to prevail; in July the number of patients suddenly increases, and is double that observed in June In August it attains its maximum, and afterwards decreases to the end of the year. The average of deaths is greater in December than in any other month. In Algeria acute disorders and pernicious fevers are not the most fatal, the greatest number of deaths being clearly due to chronic maladies. Few men escape the morbific influence of the climate; of 100 men admitted into the hospital, 6 only have been affected with sporadic diseases, 20 with intermittent fever, 20 with diarrhœa or dysentery, and 54 intermittent fever, diarrhœa, or dysentery. Diarrhœa is the most common of all, and few men escape from it. M. C. Broussais describes in the same chapter diarrhœa and dysentery—two affections united by the closest ties—caused by the same pathogenic influences—appearing at the same seasons—passing readily into each other—producing the same anatomical changes—and curable by the same methods of treatment. It is in June they are observed to increase, their frequency being observed to augment up to September, when acute is gradually replaced by chronic enteritis. After describing the morbid changes induced in the structure of the large intestine by dysentery, M. Broussais proceeded to say that he had derived benefit in its treatment chiefly from narcotics, assisted with antiphlogistic measures, purgatives proving advantageous only in mild cases. He lost no case of diarrhœa, and 2 only of 85 patients affected with dysentery; on the contrary, the mortality in chronic colitis had been very considerable. In dysentery the analysis of the blood has demonstrated the presence of no other change than the increase of its fibrine in some cases. Although dysentery is evidently, in M. Broussais' opinion, an inflammatory disease, still it is under the control of epidemic influences which must be taken into great account, and are, sometimes of so malignant a nature as to cause, at some seasons, the best directed methods of treatment to prove unsuccessful. As to intermittent and remittent fevers, they become epidemic during the hot months. In August, 1845, and in September, the patients afflicted with these maladies were four times more numerous than at any other time of the year, 396 cases of common ague fell under M. Broussais' personal observation; all did well under the influence of a regular diet, cold enemata, and sulphate of quinine in moderate doses. No deaths occurred amongst the 111 instances of remittent fever admitted into M. Broussais' wards. In all these, even when the symptoms appeared most clearly of a continuous character, intermittent phenomena could be discerned. The consideration of these two orders of fever led the essayist to speak of pernicious fevers, of which he observed 24, and lost 3; 16 of these 24 patients presented cerebral manifestations (coma, epilepsy, delirium), 4 suffered from cardialgia, 1 from hemorrhage, 1 from pneumonia, 1 from cholerie, and 1 from algid symptoms. Besides venesection, which was occasionally indicated, the sulphate of quinine appears to have been always necessary, in doses varying from a scruple to a drachm daily. M. Broussais had often seen these fevers caused by mere heat, miasmatic emanations

having nothing to do with their production. M. Broussais closed his paper with some remarks on pulmonary consumption. In 930 patients he met with, there were only 8 in whom tubercles were recognised during life; 2 of these died, 2 left the country with slender chances of amendment, and seemed to be completely cured.

ANATOMICAL CHANGES IN THE BRAIN, ACCOMPANYING THE GENERAL PARALYSIS OF THE INSANE.—Dr. Belhomme presented to the Academy two brains, one belonging to a man aged fifty-five, who died from the progress of double pleurisy, but who was affected with general paralysis. The other brain was that of a man who died of epilepsy, and who was affected with the same loss of power as the first over the muscles of locomotion. In both the grey substance was softened, also the corpus callosum, the fornix, the ventricular organs, the crura cerebri, and the cerebellum. Dr. Belhomme closed his communication with the following remarks:—The general paralysis of the insane is consequent upon softening of the cerebral substance, and this anatomical change is not only accompanied with paralysis of the voluntary muscles, but with more or less evident intellectual derangement. In seventeen cases of general paralysis, Dr. Belhomme had found the membranes always injected and adherent to the brain fourteen times. Fourteen times out of seventeen had he met with softening of the cineritious matter, and twelve times of the medullary substance. The corpus callosum and fornix were softened fourteen times; the tubercula quadrigemina thirteen times; the pons varolii and crura softened six times, and indurated in three cases; the walls of the fourth ventricle softened fourteen times, hardened three; the cerebellum and bulb softened in six patients, and the bulb indurated in three.

HOSPITAL NECKER.

[Concluded from p. 118.]

CLINICAL LECTURE. DIARRHŒA OF CHILDREN. BY PROFESSOR TROUSSEAU.

Treatment.—We have said that lientery consists in the passage of indigested food with the motions; perhaps the microscope would prove that this condition is more frequent than is generally supposed. However this may be, the little patient grows thinner, but without the presence of febrile excitement. Under such circumstances the conduct of the practitioner is exceedingly difficult, because, in the first place, the disease may be connected with an inflammation of the intestines, producing a morbid exaggeration of the peristaltic contractions, and because, in the second, we may have to cope only with a perversion of functions induced by debility; thus the symptoms may result from two very opposite conditions of the system, difficult to distinguish from each other, and each indicating a contrary line of treatment. Let us add also that it not unfrequently occurs in consequence of the derangement of some other viscus, that the intestines become inapt to accomplish their functions, and become inflamed secondarily from the presence of irritating matter on their mucous surface. Thus the duodenum, bears, without morbid excitement, the passage of chyme, but inflames when unaltered food is forced into it by the stomach. Thus also enteritis and colitis may result from lientery, originating at first in weakness. Contrary to what is observed during health, the motions of lienteric subjects are acid—a circumstance which may perhaps account for the salutary influence of alkaline medicines, by which the biliary and pancreatic secretions may be, to a certain extent, replaced. I have found three substances of this nature, particularly beneficial, these are;—Magnesia, in small doses, from one to five grains daily; lime water, one scruple to one drachm; and the bicarbonate of soda, two to eight grains.

The change in the composition of the blood, occasionally a primary, but more frequently a secondary alteration, must be remedied by appropriate means. The most efficient of all medicines for this purpose is, in my opinion, common salt, in doses varying from five grains to one drachm daily; be cautious, however, Gentlemen, how you prescribe this substance in private practice. The absurdity of the public in these matters is such that the pre-contempt; but if you order the mineral waters of Hombourg, Kissingen, or Niederbrunnen, in which the salt is really the active element, the therapeutic action will be exactly the same, and you will preserve the confidence of your patients, which a more candid prescription would most probably have deprived you of. Mineral baths, containing from two to six ounces of sulphate of iron, sulphureous or aromatic baths, with decoctions of sage, lavender, and rosemary, a pint of red wine and common salt, you will also find very effective. Above all. let the child enjoy the benefit of good air, and let him be taken into the sun. The food most appropriate to infancy is milk, a small quantity of which must be taken. Should colitis be present, it will be removed by enemata, containing a few grains of sulphate of zinc or nitrate of silver, and to remove pain, a half a drop of laudanum will suffice.

Treatment of Mucous Diarrhœa.—When the motions of the infant contain a certain quantity of glairy matter, inflammation of the intestinal mucous coating may be pronounced to exist. If the motions are greenish, and contain curdled milk, the small intestines are concerned; on the contrary, colitis will be recognised by pain during defecation by the yellow colour of the stools, occasionally tinged with blood. In these forms of diarrhœa, ipecacuanha can be exhibited once or twice with confidence, and should be followed up with saline purgatives—sulphate of soda, for instance, one to three drachms, or the double tartrate of potass and soda. In severe cases, the medicines should be continued two days in succession; if colitis accompany diarrhœa, it is necessary to act locally upon the large intestine, and this we do effectually by the injection of medicated enemata—an injection containing one or two grains of nitrate of silver to eight ounces of liquid, and ten ounces for a child over two years, should be used. A smaller quantity of fluid should not be placed in contact with the surface of the colon; and in order to ensure the proper action of the injection, the intestine should first be cleared out with a lavement of common water. But the solution will not penetrate, or will be rejected on account of the cries or efforts of the infant, unless peculiar precautions be taken; a caoutchouc tube, long enough to penetrate beyond the sphincter ani, should be adapted to the syringe, and the nates should be tightly compressed with the hand; these details may appear futile, but you will find them of great practical importance; and they should not be treated with disdain, because on these, apparently, unimportant precautions may rest the cure or loss of your patient. In mild cases, one injection a-day, for three or four days, will be sufficient; in severe cases it should be repeated twice in twenty-four hours. Sulphate of zinc or of copper, the ammonide of copper, may be also used with success; but the nitrate of silver is more generally useful. Should colic and tenesmus, indicative of colitis, or colic with borborygmi, symptomatic of enteritis, be present, half a drop of laudanum given in the drink, in the second case, or two drops injected into the rectum, in the first, should be exhibited, in order to remove pain. When the disease has lasted some days, astringents may be prescribed with advantage. We place most confidence in the extracts of monœsia, two to four grains in a mixture; or of rattany, five to eight grains.

Treatment of Choleriform Diarrhœa.—The indications of treatment are here very much the same as in the cold stage of Asiatic cholera, and the efforts of the physician should be employed rather to modify the deeply affected nervous system, than to suppress the increased intestinal secretions. Revulsion must be established on the skin by rubefacient applications, and at the same time the circulation should be roused by the exhibition of internal stimulants. Mustard poultices should be applied to all parts of the body, in succession; mustard meal should be placed between two cloths, and left only ten minutes in contact with each region. The sinapisms should be continued until a proper degree of heat has been restored to the surface. Internally the use of ammonia, as a stimulant, is not generally followed with success; the evident state of alteration of the blood in this form of disease leads us to prescribe the use of alkalies, the defibrinating influence of which is a fact admitted by every one. Alcoholic stimuli are better suited to the treatment, but ether, and the distilled waters obtained from the various families of the labiatæ, chiefly mint, and melissa (balm), are remarkably useful, probably in virtue of the quantity of camphor and essential oil they contain. The infant should take a teaspoonful of the distilled water every half hour at least, until the skin warms, the breath acquires a natural temperature, and the pulse is perceptible. This being obtained, the nervous system has been called into action, and should be left undisturbed to re-establish the equilibrium.

Ipecacuanha, both as a diaphoretic and a substitutive, is also useful, but should not be given before the reaction has fairly set in. When, by this treatment, the progress of the disorder has been checked, the disease returns to one of the other forms of enteritis, the treatment of which we have already described. Even in choleriform diarrhœa, infants should not be kept in a state of complete abstinence; they should be fed with milk and water, containing occasionally the subnitrate of bismuth, prepared chalk, or the carbonate of lime; water containing fecula, with a little egg-flip, is also a convenient article of food, and if the child rejects it at first, he will afterwards keep it down, if an extremely small quantity of laudanum be added, as a sort of "passport" to the pylorus.

The *prognosis* of the various forms of diarrhœa we have enumerated, is extremely serious for the very young infant and for the recently weaned child, but is less so when the child is still at the breast. You must not, therefore, deprive your little patient of his nurse, although pure milk may be too solid food for his deranged stomach, because it is not impossible to change its qualities. Observe the nature of the lacteal secretion in a healthy nurse. When the breast is pressed with the hand, an opaline, semitransparent fluid issues, containing few, if any, butyraceous particles; but when the child has sucked for three or four minutes, the milk rises, according the popular expression, i. e., a peculiar sensation is experienced by the nurse, and a spontaneous and abundant secretion of fatty matter takes place; the milk is then perfect, white, opaque, and highly nutritious. Allow the child to take the breast only for three or four minutes, therefore, until the milk rises, and you give him a light food, well-appropriated to his sickly condition.

If the infant has been recently weaned, his nurse should be given to him again. Some children will take the breast after having been deprived of it for six weeks; but almost all will resume it if they have been weaned only a week. If the same nurse cannot be procured, another should be tried, and the child should be given to her in the dark, because he would probably refuse the breast were he not to recognise his own nurse. At any rate, the drinks should not be given with spoon or cup; the little patient would soon refuse any more troublesome method of assuaging thirst; but he should be made to suck his drink from a twisted rag; and his drink should be made less sweet and palatable than the nurse's milk, to which he will soon, with these precautions, return with pleasure.

HOTEL DIEU.

CLINICAL LECTURE.—INTESTINAL OBSTRUCTIONS. BY PROFESSOR CHOMEL.

(Continued from page 90.)

In some instances, the progress of the contents of the digestive organs may be arrested by the presence of foreign bodies:—Thus, fruit-stones, large pieces of food, or hardened stercoraceous accumulations, have been observed to obliterate the pylorus or other parts of the intestines. In all cases of obstruction, the seat of the disease, and its nature, should first be ascertained. The vagina should be examined in females, and in both sexes the rectum should be carefully explored, in order to detect, if possible, the strangulation or obstructed portion of intestine. When the foreign body is placed on the ileo-cœcal valve, in such a manner as to interfere with its play, the symptoms have not the acute characters of common strangulation. A chronic form of obstruction is likewise produced by the development in the abdomen of tumours foreign

the intestine in their anatomical seat, but pressing upon it so as to obliterate partially its cavity. It is only of acute occlusions we intend to speak in these lectures. In these the digestive organs are found dilated above, and straightened below the obstacle, and in almost every case the morbid changes due to secondary peritonitis are observed in the vicinity of the obstruction. Occasionally the intestine is found lacerated, and issue of fæcal matter has taken place into the serous sac. It is very uncommon to find that death has been the consequence of the obstruction, without any trace ... to the peritoneum.

At the outset of the malady, no initial chill is observed. The scene opens with very acute and well-circumscribed pain, in a limited region of the abdomen. The belly becomes distended, and the leading symptoms of strangulated hernia—incessant vomiting and constipation, make their appearance. The pulse becomes frequent, and, if relief be not obtained, hiccup, the forerunner of death, is observed. The matter returned by vomiting consists at first of undigested food, soon after contains bile, shortly acquiring a sickening smell, which gradually becomes more and more analogous to that of stercoraceous matter. The constipation is not complete at first; the fæces contained in the large intestine are usually evacuated at the beginning, and it is necessary to ascertain the nature of the rejected matter before a favourable prognosis be drawn from the presence of a motion; thus, if obstruction be suspected to exist at the ileo-cæcal valve, and solid matter be evacuated, the most serious apprehensions are still justified; whereas, if a liquid stool follow a purgative, it is extremely probable that the matter has been passed from the small intestines, and that the obstruction is overcome. Gaseous products are for the most part secreted in the ileum, and after a few hours' obstruction, none are passed from the rectum; they are discharged by eructations.

The abdominal distension is not uniform; the protrusion of inflated convolutions under the walls of the belly give it an irregular shape, frequently modified by a sort of creeping movement due to successive contraction of various portions of the intestine. In some cases direct exploration of the abdomen may lead to the detection of a tumour in the precise seat of the violent pain by which the other symptoms were ushered in—a valuable diagnostic indication. The violence of the sufferings, as well as the extent of the pain, increase gradually by the production of peritonitis. The vomiting now takes place without straining, and, as it were, by a sort of regurgitation. A fatal termination is seldom delayed beyond the eighth or tenth day, but death does not inevitably close the scene, a spontaneous reduction being, in some few instances, observed in cases of internal, as well as in external, strangulation. Thus it sometimes happens that an accumulation of fæcal matter, producing obstruction, is forced away, or that the invaginated gut is liberated by gangrene, and rejected with the stools. An abscess causing obstruction by pressure on the digestive tube has been observed to burst—a favourable event, which has been followed by a cessation of the symptoms; but such examples are of too rare occurrence to justify any sanguine hopes in cases of intestinal occlusion. The diagnosis of obstruction is not in general attended with much difficulty; the disease may, however, be simulated, and hernia, when the incarcerated portion of intestine is very small, has been occasionally the cause of unavoidable error.

DAN. M'CARTHY, D.M P.

America.

SUDDEN ENLARGEMENT OF THE THYROID GLAND.—Dr. Palmer, in the *American Journal of the Medical Sciences*, describes the case of an old lady, a nun of the convent of the Sacred Heart, long subject to bronchocele, and to whom he was suddenly summoned. On his arrival he found her extended on a couch, with her shoulders elevated, and her head reclining backwards; the countenance anxious and pallid, and respiration apparently hurried. There was an enormous tumour over the region of the thyroid gland, extending out in front of the trachea, and which was reported by the lady abbess to have formed in a minute. It was at first tense and elevated; the patient complained of constant pain about the ears and back part of the head, for the sterno mastoid muscles were forced outwardly, and put violently on the stretch by the pressure of the tumour. On the second day its base began to spread laterally; it became softer, and in a few days more began spontaneously to diminish, and has since resumed the appearance of a very inconsiderable goitre. The vertical circumference of the tumour was three inches and a-half; the lateral circumference from one edge of the base of the tumour to that of the opposite edge five inches and one line. Dr. Palmer attributes the sudden increase in size of the thyroid gland in this case to the rupture of one of the thyroid arteries; most probably, however, a branch only of those arteries was ruptured; the hemorrhage would hardly have ceased so soon, and its effects became so speedily removed, had a vessel of such size as the thyroid, been pouring out blood into the parenchyma of the gland.

STATISTICS OF LOWER CANADA.—In Lower Canada there are 725 deaf and dumb; of these 447 are males, and 278 females; there are 523 blind; of these 273 are males, and 250 females; of idiots there are 950; of these 478 are males, and 472 females; of lunatics there are 308; of these 156 are males, and 152 females.

DISPUTED PERSONAL IDENTITY.—A report of a trial respecting disputed personal identity, published in the *American Journal of the Medical Sciences*, reveals an extraordinary practice in the slave states, and one which should be generally known. The plaintiff in this case, Salomé Muller, sued for her liberty before the courts of Louisiana, and her plea was that she was unlawfully kept in slavery; that she was a free woman of German parentage; that she left Germany with her parents, when about three years old, in an emigrant ship, which arrived at the port of New Orleans in the year 1818; that her mother died on the Atlantic passage; that her father died of the fever of the country a few weeks after their arrival; and that then, before she attained a consciousness of her rights, she was reduced to slavery, and from that time until the institution of the suit, had been treated, kept, and sold as a slave. Her master, Lewis Belmonti, in answer, merely put in a copy of the act of sale from John F. Miller to himself, and Miller, on being called on, denied that Salomé was white and free, and alleged her to be of African descent, and rightfully a slave. He denied that he purchased the service of her father and his children, as redemptioners, and averred that he received her as a mulatress slave in 1822, when she was twelve years old, from a man named Anthony Williams. The latter could not be found. It appeared in testimony, that a large number of Germans (1800) emigrated from Alsace to the United States. They were defrauded by the person with whom they contracted for their passage, suffered much in Holland, were nearly starved on board ship, and finally, after a great mortality among them, the survivors landed at the Balise in March, 1818. In Louisiana they were subjected to the redemption laws, sold for their passage, and scattered over the country, although a number remained in New Orleans. The mother of Salomé and an infant son died on the passage. The father, a son and two daughters, survived. A brother of the father, and a sister and cousin of his wife, with their families, were also among the emigrants. Daniel Muller, the father, and his children were carried by their purchaser to the parish of Attakapas, one hundred miles above New Orleans. His brother and family were taken to Mississippi, and the others of his relatives remained in New Orleans. In a few weeks the last heard that Daniel Muller had died of the fever of the country, and that the boy was drowned in the river. They immediately sent for the two girls, but could gain no information concerning them, and nothing was known of Salomé (1818 to 1843) until this time, and nothing is yet known of the other daughter. In the summer of 1843, one Madame Karl, a fellow emigrant in 1818, happened to be in a part of New Orleans but little frequented by any but the Spanish population, and passing the cabaret of Belmonti, looked in and there saw Salomé performing some menial service. She was so instantly attracted by her peculiar features, and their strong resemblance to those of her friends and fellow-passengers, the Mullers, that she entered the shop and began to question the young woman. In reply, the plaintiff told her she was a slave, belonging to Belmonti, and purchased from Miller. When told by Madame Karl that she was a white woman, she gave no credit to the story. Madame —, however, insisted on taking her to those whom she declared were her German relatives. She carr— her to the house of her cousin and god-mother, Mrs. Schubert, who instantly and without any previous intimation of the discovery exclaimed, "My God, here is the long-lost Salomé Muller!" As many of the German emigrants of 1818 as had any recollection of the lost girl were collected, and immediately identified her. Among the witnesses was the midwife who assisted at her birth, and who took Mrs. Schubert apart, and asked her if she recollected two very peculiar marks on the child, resembling moles, and about the size of coffee grains, upon the inner part of each thigh. Mrs. Schubert distinctly remembered these; since, on the Atlantic passage, after the mother's death, the care of the child devolved upon her, and she dressed and undressed it for months. The plaintiff was then called in, and, on examination, these marks were found. On the trial also, surgeons appointed by the court made an examination, and found them, and testified they were nævi materni, congenital, and could not have been artificially produced. As to the appearance of the plaintiff, she had no traces of African descent in her features. She had long, straight black hair, hazel eyes, thin lips, and a Roman nose. The complexion of her face and neck was as dark as that of the darkest brunette. The witnesses testified that both her parents were of very dark complexion. Salomé had been exposed, for many years of her servitude, to the sun's rays, with head and neck unsheltered, as is the custom of the female slaves. But it was proved that the parts of her person which had been sheltered from the sun were comparatively white. The broker who conducted the negotiation for the sale from Miller to Belmonti in 1838, swore that he then thought, and it always had been his opinion, that the plaintiff was white. Two or three witnesses, an old Creole woman who for many years had lived in the immediate vicinity of Miller's residence, and men who were in his employment in 1823, 1824, and 1825, identified the plaintiff, with the greatest certainty, as the same person whom they had often seen, at that time, in Miller's possession; that she was then a little girl, who spoke the English language very imperfectly, and with a German accent, and that they were told by Miller, or some of his household, that she was an orphan girl who came from a ship, and was taken by Miller from charity. For the defence in the lower courts, there was urged the improbability of the plaintiff's story—the numerous cases on record, where hundreds have testified to a person's identity, and yet it has proved otherwise; the peculiarly excitable and imaginative character of the German and the proved character of Miller for kindness to his slaves. Several persons spoke of seeing the plaintiff in Miller's possession in 1824—25, living as a slave, and perceived no German accent in her speech. Their opportunities for conversation had, however, been very limited. The main point of defence, however, was derived from the testimony as to ages and dates. The petition averred that Salomé was three years old in 1818. The defence brought forward a witness who swore that the plaintiff was delivered of her first child in 1825. It was, however, subsequently proved that the child was born in 1829 or 1830. The court decided in favour of the defendant, on the ground that he could not divest a citizen of his property, upon such testimony of identity as that offered by the plaintiff—although he admits that the resemblance to the Muller family and the congenital marks, were a very remarkable coincidence, and further said he was satisfied, from the evidence of the plaintiff's delivery in 1825, that she was not the lost Salomé. An appeal was made to the Supreme Court of Louisiana, and the case came up in May, 1845. In the meanwhile, the Consul for New Orleans from Baden-Baden had visited Europe, and brought back with him a certified copy of the registry of birth, from which it appeared that Salomé was born on the 10th of July, 1831, and therefore,

in 1818, was five years old and not three. The cause was argued by numerous counsel, and on the 21st of June, the court decided that they were fully satisfied that the plaintiff was "Salomé Muller," and if not so, if there was another person, of the same age, with the same peculiar marks, and bearing so strong a family resemblance, "it would be one of the most wonderful facts in history." She was therefore declared free. *** It thus appears from this very remarkable trial, that despite the accumulated evidence poured in on all hands, in addition to the physical evidence offered by the presence of the nævi materni, and the undoubted proof that the plaintiff was a white woman, and neither a mulattress nor a negress, the lower court of Louisiana, in its tender regard for the sacredness of property in human beings, could decide in favour of the defendant notwithstanding the great discrepancy in the evidence as to dates, it being proved that the dates furnished by the defendant's witnesses were altogether incorrect. An additional fact connected with the case, and one which it is necessary should be generally known, is that persons going to the slave states in America, unless fully able to pay all their travelling and other expences, are liable to be sold into slavery as redemptioners, and then may be so transferred from one dealer in human flesh to another, as to lose all chance or prospect of obtaining such a chain of evidence as would establish their claim to freedom.

TURPETH MINERAL.—Dr. Hubbard of Hallowell, Maine, in the Transactions of the Philadelphia College of Physicians, records his experience with the turpeth mineral, the sub-sulphate of mercury, as a safe, and certain emetic, unpossessed of cathartic action. He has found it, he says, of great advantage in croup, especially in the spasmodic and intermittent forms, and in scarlatina maligna. In commenting on the peculiarity of this substance as an emetic, and in answering some of the objections urged against it, Dr. Hubbard remarks that in the first place the promptness and certainty of its operation belong to no other substance that he is acquainted with. It has seldom, if ever, failed to vomit efficiently, when administered in a proper dose, in any of the various conditions of the stomach, and of the system, in which he has given it. It usually acts in ten or fifteen minutes, and the dose should be repeated at those intervals, if the first fail, which rarely happens. In efficiency and revellent power, it is not, perhaps, quite equal to the tartarised antimony; it is, however, vastly superior, in these respects, to ipecacuanha, or any other substance. In safety, it is greatly superior to antimony. Its emetic operation usually continues from an hour to an hour and a half, not accompanied nor followed by any of the distressing nausea, prostration, and depletion, of antimony; but, on the contrary, leaving the patient with the invigorated feeling arising from equalised warmth and circulation In its emetic operation, it has seldom, never in his recollection, been accompanied or followed by catharsis. He has never known it to be violent, nor otherwise than entirely safe in its operation, although he has given it in much larger doses than are usually directed; nor has he ever seen salivation follow its use as an emetic. So safe does he consider it, that in urgent cases he has not hesitated to put his patient under its full emetic operation, two or three times within twenty-four hours; nor has he seen ill consequences result from such practice. He thinks that the dose should be somewhat larger than is usually recommended. From two to three grains may be given to a child two years old, and repeated in ten or fifteen minutes, until emesis is produced If the first dose fail, the second usually acts as soon as it reaches the stomach In this country turpeth mineral is rarely used on account of the violence of its action.

England.

RENAL DISEASE.—Dr Fife, in his report on the diseases treated at the Sunderland and Bishop-Wearmouth Infirmary, published in the *Provincial Medical and Surgical Journal*, says that renal diseases are of frequent occurrence in that locality. The cause of this is probably to be met with in the occupations of those principally affected, rather than in any endemic or topographical peculiarity. A large proportion of the cases occurred in ship-carpenters, seamen, glass-men, and ironfounders, in all of whom the function of the skin is liable to both frequent and serious interruption. When to this fact is added the recognised connection or relation subsisting between the cutaneous transpiration and the secretion of urine, a very satisfactory explanation is afforded of the frequency of urinary diseases. Another cause which has been supposed to operate in the causation of diseases of the urinary system, is the nature of the water with which the town is supplied, and which contains a considerable quantity of saline and earthy matter, especially lime. To this source he does not, however, ascribe much importance, as were it really an active agent, the cases in all probability would have been more frequent in occurrence, and different in character. By far the larger portion of them partook of the subacute or chronic inflammatory nature, being accompanied by both the symptoms and condition of urine known to denote such state of the kidneys, and which circumstance is quite consistent with the very common and obvious cause to which allusion has already been made. So far as the urine was tested, it exhibited the usual deviations from its healthy condition. In some cases albumen was present in considerable quantity; in a majority acid preponderated; whilst in a few an alkaline redundancy prevailed, which last state was perhaps in some degree attributable to the treatment, in which alkalies formed a prominent feature. The treatment consisted principally in alteratives, aperients, the preparations of soda, potass, and magnesia, with hyoscyamus, counter-irritation by means of the antimonial ointment, croton oil, turpentine, and in a few of the more acute cases, topical blood-letting and blistering, the unpleasant effects of the latter being, as far as possible, obviated by the exhibition of anodynes and diluents. In a later stage of the disease, in many instances, turpentine and copaiba in small doses were of the very highest utility. When the inflammatory action had been fully subdued, tonics, and more particularly the preparations of iron, were generally given with benefit. Three cases of diabetes mellitus were treated by Dr. Fife. One terminated fatally; another continued to linger at the date of the report; and the third, a young woman, was apparently cured by medicine, the symptoms of the disease not having returned for a twelvemonth. With respect to this disease, Dr. Fife agrees with those who regard it as not essentially referable to the urinary organs, but, on the contrary, dependent on some peculiar morbid condition of the organs by which digestion is carried on. The following circumstances seem corroborative of this opinion:—The almost universal presence of dyspepsia, which, when the history of a case is thoroughly sifted, will be found to have existed for some time before the increased flow of urine attracted attention; the effects of remedies, medicinal and dietetic; and above all, the appearances met with on dissection of those who have died of the disease. The first proposition acquires strength from the well-known influence of defective or depraved action of the assimilating organs over other secretions; wherefore it is no stretch of analogy to infer a similar effect on that of the urine. The second derives support from the utter inutility of those remedies, which are admitted to act most beneficially in diseases of the kidneys and bladder, in cases of diabetes. The last from the fact, that the anatomical changes in the urinary organs, found after death in those who have died of diabetes, are in no degree commensurate with the functional disorder, if such were confined to the kidneys, which in three cases examined by him, displayed *no change of structure;* whilst the stomach and assistant viscera were unequivocally and organically diseased. That such should be the case might be safely inferred, even during life, from a variety of circumstances which were present, to a greater or less extent, in almost every case of diabetes which he saw. Amongst the most prominent symptoms of the disease are, morbidly increased appetite for food; incessant and insatiable thirst; dry, parched, and harsh skin; the tongue red, dry, streaked with mucus, but more commonly presenting a general raw appearance, as if deprived of its ordinary membranous covering, the papillæ being partially, if not entirely, obliterated. To these may be added the dry, lank, and woolly state of the hair, and also an almost indescribable appearance of the sclerotic coat of the eye. The alvine discharges are, except when aperients are given, scanty and very irregular, taking place at the lapse of two, three, or four days, and sometimes at much longer intervals of time, and invariably exhibiting a marked deficiency of bile; when, however, an active purge, as a full dose of the castor oil, is given, the quantity of the discharge is frequently enormous. To such accumulation of feculent matter is to be ascribed the irregular unyielding hardness of the abdomen, which may or may not be accompanied by distension. All these symptoms tend to show that whatever part the kidneys may play in this very formidable disease, the digestive system at large is more than secondarily implicated, if not the absolute *origo mali.* The appearances met with after death were confirmatory of this view of its pathology, being almost entirely, so far as any actual change of structure is concerned, strictly confined to the stomach and its assistant viscera, whilst the only changes met with in the kidneys were the following, which cannot be properly regarded as constituting organic lesion:—In one of the cases both kidneys were paler in colour, flatter, and more flaccid than in the natural state; their substance was less firm, but not to such an extent as to render the term softened justifiable; both the pelves and the infundibula were enlarged, many of the latter obliterated; no trace of inflammation was present. The stomach was of its normal size, but its coats, even before it was cut into, were most evidently attenuated; when it was opened the villi were in every part wanting, the whole surface presenting the appearance of a highly inflamed and congested membrane, being smooth, except in one or two small patches where ulceration had occurred, the vascularity generally arborescent, but in many places assuming the aspect of extravasation beneath the membrane. The whole mucous coat was soft and pulpy, being readily removed by the finger nail, when even lightly used. The muscular coat was hardly discernible, whilst the peritoneal or serous presented no unusual change. In this case the pancreas was larger than natural, flabby, and easily torn; in another case this gland was harder than in health. The liver was paler than in health, and somewhat softened, but not to such an extent as to lead to the belief that such change was the effect of disease, but perhaps more properly attributable to the gradual wasting and exsanguined state of the system consequent thereon. The gall-bladder contained a small quantity of dark-coloured viscid bile. The mucous lining throughout the intestinal canal was more or less vascular, and in many points ulcerated; this last appearance probably had no direct part in the disease which forms the subject under consideration, but rather occurred as it does in phthisis and other diseases which terminate in hectic. The foregoing statements all refer to the case of a female, with the exception of the remark, that "in another case the pancreas was hardened." She had suffered long from the disease, and died apparently from some sudden and serious lesion of the brain, which unfortunately was not examined, owing to the close approach of the interment, which was fixed for the same day. In one of the other cases only was there anything unusual met with in the kidneys beyond what has already been noticed: this was simple venous congestion. The treatment which Dr. Fife has noticed to be the most beneficial, has been that addressed to the digestive system, and consists in the employment of alteratives, sudorifics, chalk, iron, and occasional aperients. In most cases calomel is to be preferred to any other mercurial, and it may be advantageously combined, either with tartrate of antimony, or Dover's powder: where there appears to be much gastric irritability, Dover's powder has the best effect, and if the tartrate of antimony be used, it should be given in combination with either opium or the hydrochlorate of morphia, either of these combinations affording at the same time the best chance of acting on the skin. In this disease, however, diaphoretic medicines seem to have but little power, and should, therefore, where it can be procured, be assisted by the warm bath, which may,

provided there be not great debility present, be employed on alternate days. Whilst the red state of the tongue continues, Dr. Fife has given the chalk in full doses with very decided benefit, generally alone, but sometimes in conjunction with the Dover's powder. So soon as the irritability of the stomach has been somewhat diminished, the sulphate of iron, with or without quinine, has been used, and great improvement has been the result; another very useful formula is the citrate of iron with quinine in solution, or in a simple bitter, as the quassia. For common drink, where, as is generally the case, the thirst is urgent, one part of lime water with two or three of milk, both allays this distressing symptom, and also acts beneficially on the lining membrane of the stomach. The diet of diabetic patients should be chiefly composed of animal food, as beef and mutton, in the form of chop, or steak, with as little bread or vegetable as possible, and where the state of the stomach does not forbid it, wine or malt liquor may be allowed. Dr. Fife does not think that bread, when taken in small quantity, produces the bad effects attributed to it by many; at the same time the most manifest injury arises both from it and vegetables when taken in the ordinary manner.

Spina Bifida.—Dr. Barclay, in the *Provincial Medical and Surgical Journal*, details the case of an infant, labouring under spina bifida, respecting which he was consulted. The tumour was situated on the back part of the head and neck. He then gave no hopes of the infant's surviving. He was again requested to see the child, in conjunction with Mr. Derington, when it was eight weeks old. It presented a most singular appearance, particularly in the erect posture; a large vascular bag, filled with fluid, and nearly the size of the child's head, hung from the occiput, and by its weight, though it partly rested on the shoulders, the cervical vertebræ were considerably displaced, and the head drawn backwards. The pedicle by which this bag was attached, was extremely short and flat, about an inch in width and a line in thickness; to the feel, like a fold of skin, and only in the centre appearing to have any connection with the cranium, over which it was moveable, except at this point. No perforation nor imperfection in the bone could be detected; and when very considerable pressure was exerted on the bag, no effect was produced on the child. They, therefore, determined on evacuating the sac, and six ounces of clear yellow serum were drawn off, but no further light was thrown on the nature of the case, while the child seemed relieved by the removal of the load. It then had exactly the appearance of a wrinkled empty scrotum hung on to the occiput. In three days it was found to have filled again considerably, and they then determined to try to rid the child of this unsightly deformity; Mr. Derington passed a double ligature of strong silk twice through the flat pedicle, and tied the loops on either side, and the remaining one in the centre, with very considerable force, though not sufficient to strangulate it completely; about three ounces of fluid similar to the former were evacuated. On the next day the ligatures were tightened; and on the fourth day, the pedicle being partly ulcerated through, fresh ones were applied, so as to strangulate the sac completely. Two days afterwards it had sloughed, and was so offensive that Mr. Derington removed it close to the ligatures; it appeared lined internally with a glistening membrane. The child looked well and healthy the next day, and as the administration of "Godfrey" had been discovered, and strictly prohibited, it put on a thriving appearance, but was seized with convulsions two days afterwards, and died the same evening, with all the symptoms of effusion within the cranium. A scanty permission was obtained to examine the seat of disease only. About a line above the os occipitis was a foramen about the size of a crow-quill, giving passage to a cord like the vas deferens. It did not appear pervious, but a single probe could be passed obliquely downwards through the foramen, quite to the posterior part of the medulla oblongata. The occipito-parietal sutures were hurriedly ripped open, and the occipital bone forcibly reflected, when the channel was seen to be connected with the dura mater, but the impatience of the persons present prevented the possibility of the relative position of the parts being more satisfactorily observed. The brain and its membranes were loaded with serum, which flowed in considerable quantity from an incision penetrating to the ventricles.

Iliac Abscess communicating with the Rectum and Bladder.—Mr. Russell describes, in the *Provincial Medical and Surgical Journal*, the case of a man, fifty years of age, who, after suffering from supposed rheumatic pains in the back, and left hip, and thigh, had pain in making water, with frequent micturition, which was followed by the formation of a large tumour in the lower part of the abdomen, on the left side, and the setting in of irritative fever. When first seen by Mr. Russell, the tumour was large and prominent, and occupied the whole of the left iliac region, extending a little across the median line, and obliquely upwards, nearly to the lower edge of the left ribs. It was firm and tender, but the abdomen in other parts was flaccid, and free from tenderness. Soon afterwards pus was discharged both by the urethra and by the rectum. The patient next became hectic, and the soft palate and tonsils aphthous. The tumour afterwards burst externally, and discharged a large quantity of very fetid pus. This was succeeded by the discharge of urine and fæces through the wound, and at last the unfortunate man sunk exhausted. The body was examined eighteen hours after death. The abdomen alone was examined; the surface of the viscera was perfectly healthy; not a trace of any abnormal matter in the cavity. All the viscera healthy, with these exceptions:—There was singular absence of blood; the rectum took a very unusual course; it passed from the termination of the colon in place of at once descending into the pelvis, towards Poupart's ligament, adhering to this part of the anterior wall of the abdomen by cellular bands, and thence descended abruptly into the pelvis, forming an acute angle, situated a little above Poupart's ligament, and rather internal to the middle point; surface of the rectum quite healthy; a considerable quantity of fat surrounded the adhesions and the gut. The integuments were separated from the muscles in the left iliac region of the abdomen by the cavity of the abscess, which was nearly empty of pus, but with the walls in a state of slough. From these parts the abscess passed behind the horizontal ramus of the pubes, entirely separating the bladder from its anterior connections, in front of Poupart's ligament into the iliac region of the thigh, deep among the muscles towards the bone, and also occupied the iliac fossa, having raised the iliac fascia from its connection with the muscles, infiltrated the iliacus internus and psoas with sanious pus, and extended along the psoas as high as its origin from the spine; at the highest point the pus was of a healthy character, and was strikingly contrasted with the sanies contained in the rest of the abscess. The bones in the neighbourhood were examined most carefully, and were found not to be denuded; the ilium was covered throughout by its periosteum, and the spinal ligaments were not at all invaded. On laying open the rectum, an ulcer was discovered at the acute angle formed by the gut, near Poupart's ligament, which communicated with the cavity of the abscess by a short passage through false membrane; the adhesion in this part had become so much weakened that in a day or two, had life continued, the ulcer must have opened into the cavity of the abdomen. It had evidently commenced from within, the mucous membrane being destroyed for the space of a shilling, whilst the opening in the side of the gut was not larger than the section of a pea; the mucous membrane of the rectum was injected, but otherwise healthy; the mucous membrane of the large intestines, and of the cœcum, together with the lower portion of the ileum, were healthy. Bladder healthy, excepting a small ulcer, large enough to admit a large probe, in its left side, which opened into the abscess through a short sinus; in this case the absorption of the coats had proceeded to a greater extent on the outside; the bladder contained some urine, loaded with pale lithates, but apparently without any pus. Iliac vessels healthy. Some atheroma in the abdominal aorta.

[The folllowing are the only articles of interest to the profession in the last two numbers of the Lancet.]

Encephaloid Disease of the Peritoneum.—Some brief details of a case of ascites are reported from St. Bartholomew's Hospital, in which dissection revealed the existence of encephaloid disease of the peritoneum. The fluid drawn off by paracentesis on the first occasion, coagulated spontaneously. The right lower extremity was œdematous before death. The autopsy was made nine hours and a half after death, when the body was still warm, the limbs all lax, and the blood generally coagulated. Head not examined. Some old adhesions of the left pleura about the base; no notable quantity of fluid in the left pleural cavity; right pleura free, the cavity containing about a pint of clear serum. The right half of the upper surface of the diaphragm was studded with little, round, polished, white elevations; no such deposit existed on the left side. Base of the right lung slightly contracted, and the pleura wrinkled; both lungs were gorged with blood behind, but no deposit existed anywhere in them. The cellular surface of the reflected layer of the pericardium, behind the sternum, had a few white nodules attached to it, of the same character as those which grew upon the diaphragm. The serous surface was smooth, the cavity containing a few drachms of clear fluid. Heart small, healthy. The rectus abdominis was seen to be full of white, opaque granules, especially at its attachment to the thorax; peritoneum contained a large quantity of clear fluid, in which floated a single flock of whitish fibrin, like an ostrich feather; the layer lining the walls of the abdomen was thick and tuberculated with a hard, white deposit. On the removal of the fluid, the small intestines were seen running down the centre of the abdomen in a spiral coil, tightly bound to the spine by a thickened and short mesentery, and to one another by an adhesion here and there between the folds. They were of a faint purple tinge, with a mottled-white, tuberculated deposit upon the serous surface. The liver was coated with a thin, white layer of fibrin, and adherent to the stomach, between which and the colon lay the great omentum rolled up into a white, hard cord, appearing on section to be composed of little grains of fat, from between which a creamy fluid exuded on pressure. From about here, two or three round cords, containing pervious vessels, passed to the front of the abdomen. The tuberculated deposit was confined exclusively to the serous membrane; it was in some places as thick as a crown-piece, but in no part was the muscular coat implicated, and the mucous membrane was healthy throughout, although the form of the intestinal canal, and particularly of the stomach, was very much altered by the rigid case in which they were partially enclosed. The duodenum, where it has no serous covering, was quite free from any lesion of the kind; while all the rest of the intestines, the stomach, and the mesentery, were dotted over with nodules of this sort, from the size of a split-pea to that of a broad-bean, or even larger—all hard, and with polished surfaces, none giving issue to any fluid on pressure. Liver adherent, except at the thin edge: internally it was healthy, but the gall-bladder was studded with numerous deposits. Spleen and kidneys healthy; mesenteric and lumbar glands enlarged, white, hard, but giving issue to a creamy matter on pressure. The right inguinal glands, and one absorbent gland between the axilla and the mamma, had also undergone the same degeneration. Veins of right thigh healthy. A small cyst existed in each ovary, larger in the right, and holding about four ounces of a thick, brown fluid; the peritoneal surface, but not the cystic, was tuberculated as above. These cysts rose above a hard floor of thickened peritoneum, extending from the ossa pubis to the rectum, having no traces of the fossæ usually found there. Below this the uterus lay imbedded in a hard, tough, cellular tissue, in which were a few spots of deposit, such as existed elsewhere; but the uterus itself was quite free from them: it was bent into a curve, the concavity forwards, the mouth slightly vascular. The fluid withdrawn in this case spontaneously coagulated on the first and not on any subsequent occasion. The same spontaneous coagulation was observed in a case of cancer of the peritoneum lately treated in Addenbrooke's Hospital, Cambridge. But so far from this being diagnostic of the disease, Cruveilhier has found the fluid bloody and turbid in cases

of cancer of the omentum, where the fluid was probably secreted under conditions analogous to those in the case detailed; and in the dissection of a case of cancer of the peritoneal surface of the colon, accompanied by ascites, occurring in the practice of Mr. Paget, the fluid was most singularly limpid and colourless. In the above case, the tendency of the disease to attack serous membrane was displayed in the pericardium and right pleura, as well as the peritoneum. The affection of the pleura, and accompanying effusion, is interesting in connection with Sir B. Brodie's remarks on pleural effusion, as being the common mode of termination of protracted cases of mammary cancer. Here, however, were no scirrhous tubercles in the lungs; they were found only on the diaphragmatic pleura. In another case the encephaloid disease affected principally the omentum. The patient was a female, aged fifty-one years of age, who had a swelling in the left inguinal region, which was greatly increased by injuries inflicted by a horse, which trod on her abdomen. When admitted into the hospital the abdomen was irregularly conical in shape, the umbilicus being the apex of the cone. A large round swelling could be felt in the left iliac fossa, and a smaller, less defined, in the right. Some parts of the abdomen were soft and yielding; in other parts there were small, round, hard, and freely-movable tumours, tender on pressure, and extending as high as the epigastrium. The patient lived only two or three months after she entered the hospital. The body was much emaciated; heart small, and retaining a little fat about the apex only; lungs healthy, but traces of recent pleurisy on the left side. A singular appearance was given to the contents of the abdomen by the omentum, which, thickened and as white as if painted in parts, extended a tough edge from the right hypochondrium to the left iliac fossa, where it became connected with a white mass of similar composition, filling the pelvis, and re-appearing in the right iliac fossa. This mass was soft and pulpy, making a white turbid mixture with water; and when the fluid parts had been thus washed away, there remained a hard, white, elastic, fibrous tissue, constituting the body of the tumour, into which the white creamy fluid had been infiltrated. The lining membrane, and part of the thickness of the walls of the uterus, was healthy, but the outer surface of its walls had imperceptibly become implicated in the degeneration of the surrounding parts. A patch of the same kind of matter existed on the coat of the gall-bladder, but no traces of similar degeneration elsewhere, the serous surface of the stomach and intestines being quite healthy. Carcinoma of the substance of the uterus not affecting the mouth of that organ, is the most striking single fact illustrated by the above case. As compared with the previous case, the chief point of interest is the result of the different dispositions of the omentum. Had fluid been effused from the beginning, and the omentum rolled up in a cord, as happens in chronic peritonitis, the resemblance of the two cases in detail would have been very close, so much does the after progress of disease depend on the order in which any of the earlier processes have succeeded each other. In one point, these two cases differ widely from each other; the affection seemed in the former to attach itself particularly to the serous membranes; in the latter, the omentum was almost the only part of the peritoneum affected, although so broad a surface was presented on which this morbid product had been developed. As the omentum seems to be the part of the peritoneum most susceptible of cancerous degeneration, judging from recorded cases of cancer affecting this part only, so it is most probable that the morbid process going on in the ovarian tumour was communicated directly to this more susceptible part, rather than to the serous membranes of other parts around. Thus, in a man who died in the hospital in 1842, of extensive cancer of the stomach, the omentum was the sole portion of the peritoneum much implicated, only a few carcinomatous tubercles existing at the bottom of an old hernial sac, excited, as it appeared, by the irritation of the pressure of a truss.

Presumed Injury of the Axillary Artery. —A man was admitted under Mr. Quain into University College Hospital, with a lacerated wound, about an inch in length, in the left axilla, from which arterial hemorrhage (according to report) had issued to the extent of two quarts. It had ceased spontaneously. Pulsation was distinctly felt in the left radial, but the next day no pulsation could be distinguished in any of the ateries below the wound Five or six days afterwards a feeble pulse was felt in the radial artery, and, from this time, the case progressed favourably, the wound granulated kindly, and was perfectly healed at the end of three weeks, when he was discharged. He returned to the hospital a few days afterwards, complaining of pain over the back part of the shoulder, for which the belladonna plaster was ordered. He stated that the temperature of the left hand appeared to him to be less than than that of the right; the thermometer indicated for the left, 91 deg., for the right, 93 deg. In a clinical lecture, Mr. Quain observed that the important point in the foregoing case was the fact that, notwithstanding the occurrence of profuse hemorrhage, and the injury of the main artery of the limb (as shown by the cessation of the pulsation in the arteries beyond the seat of injury), the patient did well, without any interference by operation or otherwise. There was a want of evidence for forming a positive opinion as to the source whence the hemorrhage proceeded; for, as the patient was not seen by any medical practitioner till after the bleeding had ceased, there was no evidence on which reliance could be placed, either as to the manner in which the blood had issued from the wound, or as to the character of the blood itself, and there was not therefore sufficient means of judging whether it escaped from an artery or from a vein. The amount of hemorrhage was doubtless exaggerated, as is usual with patients and their friends in cases of wounds. He was of opinion, after the recovery of the patient, that the axillary artery was not the vessel from which the blood had escaped, because the hemorrhage soon ceased, and did not recur. No tumour had formed at the seat of injury, and the pulse was for some time perceptible below the wound. It should be stated that the condition of the pulse in the two arms was not compared after the patient's admission into the hospital, but the surgeon and the dresser concur in stating that the pulse in the injured arm was an ordinary one. When Mr. Quain saw the case next day, the pulse at the wrist was not perceptible. On a review of all the facts, at the fortunate conclusion of the case, it appeared probable that the vein had been wounded and that the artery was obliterated in consequence of having been contused by the end of the rail; it was admitted that the reasoning is not to be considered by any means conclusive. Fortunately for the patient, no opportunity arose of clearing up the doubt. If arterial hemorrhage had occurred, Mr. Quain intended to divide the pectoral muscles over the track of the wound, and secure the bleeding vessel at each side of the opening into it; the hemorrhage would in the mean time have been commanded by pressure above the clavicle, and by an assistant's finger within the wound. *** From this last paragraph it would appear that Mr. Quain is in favour of the plan of proceeding recommended by Mr. Guthrie, and in direct opposition to that adopted by his colleague, Mr. Liston, although at the meeting of the Royal Medical and Chirurgical Society, he expressed a qualified approbation of Mr. Liston's operation.

Dislocation of the Humeri.—A case of simultaneous dislocation of both humeri from a fall is reported from St. Bartholomew's hospital. The nature of the injury was not discovered until a fortnight after the accident. The left humerus was dislocated under the pectoral muscle, and the right into the axilla. The right limb, however, performed its movements so freely that no one at first conjectured that it was injured. Reduction was readily effected, and the patient did well.

Penetrating Wound of the Chest.— A case of penetrating wound of the chest, in which the lung was apparently wounded, is reported from St. Bartholomew's hospital. The patient stabbed himself several times in the chest just below the left nipple with a carving fork. Emphysema ensued, and the man complained of a weight at the chest in breathing. The wounds were dressed simply; the emphysema gradually disappeared, and the man was discharged cured in a fortnight. Mr. H. Coote remarks on this case that some surprise may be experienced how a sharp instrument, penetrating the cavity of the chest to the depth of three and a half inches just below the left nipple, and wounding the lung, could have missed injuring the heart and pericardium. The heart, an organ of variable size; is separated from the walls of the chest in this situation by the thin edge of the left lung, which rests upon the pericardium. An instrument entering at the left nipple, and directed obliquely outwards and backwards (as would be the case if the patient were right-handed), would pass from this portion of lung to the left of the heart, into the general pulmonary tissue.

Lacerated Wound of the Elbow-joint.— A case is reported from St. Bartholomew's Hospital of lacerated wound of the elbow-joint, with separation of the external condyle of the humerus, occurring from an accident by machinery, in a boy, eleven years of age. The external condyle was removed, and the arm set at right angles. Partial sloughing took place, but the slough separated, and the wound healed by granulation, the arm remaining fixed at a right angle.

Compound Dislocation of the Knee-joint. —A case of this injury is reported from the Tunbridge Wells Infirmary. The patient, a labourer, twenty-one years of age, whilst working in the railway tunnel near this place, fell from a scaffold, a height of ten or twelve feet. A heavy piece of timber falling after him, appears to have struck him on the front of the lower part of the femur; and the upper part of the leg lying at the time across an iron rail, a compound dislocation of the tibia forwards was caused, the internal condyle of the femur being driven through an extensive wound in the popliteal space, the external condyle, resting on the posterior part of the head of the tibia. The leg being bent forwards and outwards, the tibia appeared to be twisted somewhat laterally; the patella was pushed upwards, its inferior edge directed forwards, and its posterior surface resting on the articulating surface of the tibia. A depression was perceptible superiorly; the limb was shortened about an inch and a half; the leg could be slightly rotated inwards or outwards, more particularly outwards, but not flexed until after the reduction of the dislocation, which was, however, easily effected. There was profuse hemorrhage at the time of the accident; no pulsation could be felt either in the posterior tibial or in the tarsal artery. The surgeon first in attendance, after reducing the dislocation, and having carefully closed the external wound with sutures and adhesive plaster, applied a bandage over the whole; it was deemed prudent to wait before deciding on amputation. Three days afterwards it was evident that no adhesion had taken place; moreover, considerable constitutional irritation had set in, and on raising the leg to remove some of the dressings, a sudden gush of blood, evidently from a very large artery, determined Mr. Hargraves to amputate immediately. The limb was removed, by means of the flap operation, at the lower third of the thigh, but, apparently owing to the great loss of blood sustained at the time of the accident, the poor fellow rapidly sank, and died five hours after. Dissection of the injured parts: on removing the integuments, great extravasation of blood was found, quite filling up the popliteal space, and extending nearly to the ankle. Both heads of the gastrocnemius were extensively lacerated; the internal quite torn through; the popliteus torn across; the semi-membranosus lacerated; the tendinous expansion forming the ligament of Winslow torn into shreds, but the round tendon not injured; the biceps very slightly injured; the tendons of the sartorius, gracilis, and semi.tendinosus quite perfect. The popliteal artery was lacerated to the extent of half an inch, but not torn quite through, and (as was apparent when the joint was re-dislocated) pushed together with the vein and nerve external to the outer condyle of the femur. The internal lateral ligament was torn from its attachment to the femur, carrying with it a small portion of bone; the external lateral ligaments were not injured; the external or anterior crucial ligament was torn through, but the internal or posterior crucial ligament was not injured; the aponeurosis supplying the place of a capsular ligament, besides being extensively torn behind, was also ruptured in front, just external to the ligament of the patella,

where a portion of the head of the tibia had protruded. Mr. Yate, the reporter, says there are several points of great interest in this case well worthy of notice. It appears at first astonishing that fatal hemorrhage had not been the consequence of such an injury to the popliteal artery, but the fact of this vessel being put upon the stretch and firmly compressed over the external condyle of the femur, and a coagulum having formed around the injured part, will efficiently account for the cessation of the bleeding; a state approaching deliquium animi no doubt also favoured this circumstance. The displacement of the internal condyle was such as could not possibly have occurred without the rupture of the internal lateral ligament, which, arising from the internal condyle of the femur, passes downwards and forwards to the head of the tibia, but the external lateral ligaments, which arise from the external condyle, and descend backwards to the head of the fibula, were not necessarily injured. Again, the anterior or external crucial ligament, which arises from the posterior part of the external condyle, and descends obliquely forwards to the fore part of the head of the tibia, was as might be expected, ruptured; but the posterior, or internal crucial ligament, which arises from the fore part of the internal condyle and descends vertically, or rather backwards, to the head of the tibia, was not injured. The leg could be easily rotated outwards, owing to the complete separation of the internal lateral ligament; but the rotation inwards was very circumscribed, owing, doubtlessly, to the resistance offered by the external lateral ligaments, which were unbroken. Sir A. Cooper relates a case of compound luxation of the femur backwards and outwards, where neither the lateral nor crucial ligaments were ruptured; but in his case, the external condyle was driven backwards and outwards, the internal condyle being thrown forwards upon the head of the tibia—a state of things which will be seen to be exceedingly probable, if we consider the anatomical relation of those parts. In conclusion, the above case, in Mr. Yate's opinion, goes far to prove the propriety, perhaps the necessity, of immediate amputation in a compound dislocation of this joint; for surely Nature cannot be expected to repair so serious and extensive an injury. *** There cannot be a doubt that amputation ought immediately to have been had recourse to.

Malignant Diseases of the Stomach.—A case of encephaloid disease of the pylorus is reported from St. Bartholomew's Hospital, in which during life there were not any symptoms of a diseased condition of the stomach, except a most voracious appetite. The patient was admitted into the hospital, on account of weakness and tremors, partly perhaps arising from habitual intemperance, and partly from his occupation, that of a looking-glass silverer. Four days before death he was seized with pain in the head, vomiting, thirst, and loss of appetite. The body was examined twenty-four hours after death. Arachnoid white and opaque, with little white dots in the meshes of the pia mater. Substance of the brain soft, with numerous bloody points, and little vessels full of coagulated blood, drawing out like hairs on suction. The arteries about the base were thickened, and yellow in patches. The pleuræ were extensively adherent; the lungs generally emphysematous, œdematous, and posteriorly rotten, readily tearing down under the fingers. Beyond the enormous deposit of fat about the heart, and the deep staining of the lining membrane on the right side, there was little to notice in that organ. The peritoneal surface of the stomach was dusky, and injected near the pylorus; the mucous surface was red and rough, especially towards the pyloric end of the organ. The mucous membrane here, as in the upper part of the duodenum, was emphysematous; the sub-mucous cellular tissue of the stomach infiltrated with a creamy fluid, by which it was widely separated from the muscular coat, the whole of the coats together forming a thick membrane, traversed by fine striæ parallel to each other, at right angles to the axes of the stomach. The emphysematous condition of the mucous membrane tended much to obscure the particular local changes that it had undergone; but a small, white, fungous growth was attached near the pyloric end of the minor curvature of the stomach, while a ring of the same substance, presenting an appearance very like that of psoriasis, lay near the same place. There is nothing to notice in the small intestines or mesenteric glands. The liver was large, indented by the pressure of surrounding parts, and, as viewed by the microscope, in a state of commencing fatty degeneration. A few cartilage-like bodies, small, with opaque spots and striæ, without any enveloping membrane, were scattered beneath the capsule, and throughout the substance of the organ. A lobular mass of fat, partly crossed by fibres of the cremaster muscle, lay attached to the spermatic cord on each side, chiefly external to the inguinal ring. Next follow the details of a case of scirrhus of the pylorus, the principal symptoms being continued and severe vomiting, constipation, extreme progressive emaciation, and the presence of a large quantity of urea in the urine. The body was examined thirteen hours after death. Lungs generally emphysematous; the black pulmonary matter on the surface contrasting strongly with the pale-white colour of the rest of the organ. Within, they were œdematous, breaking down readily under the finger, but resisting traction well. A small pulmonary abscess existed near the apex of the left lung, close beneath the pleuræ. Stomach more than four times the ordinary size; externally healthy; within, stained of a dirty purple, and coated with thick mucus, beneath which, the mucous membrane appeared entire, but *mamellonnée* in an extreme degree—this towards the pylorus; at the cardiac ends the coats were partially digested. The stomach contained a large quantity of the same kind of fluid as had been vomited during life. The pylorus was contracted—so as hardly to allow the passage of a common pencil—by means of a hard ring projecting all round, single on the side that lay uppermost, but on the side nearest the pancreas double, the two ridges leaving between them a cavity big enough to contain a hazel-nut. Perhaps the whole morbid growth was not more than an inch and a-half in diameter, the pyloric orifice of the stomach lying in the middle of the thick ring. Some small, white, hard bodies were found in the gastro-splenic omentum; none elsewhere. The mesenteric glands were rather large, but grey, and of natural consistency. Except a little black dotting of the follicles of the colon, the intestines were generally healthy. There can be little doubt that any other mechanical obstacle, acting to the same extent, would have produced analogous results by vomiting and progressive emaciation; for the scirrhous substance, in the present instance, had not undergone any change by ulceration on the surface; it was merely a hard annular mass, which, but for the little bodies in the gastro-splenic omentum, could hardly have been ascertained to be of scirrhous nature, the existence of these little bodies being the only evidence that the pyloric disease was not purely local; yet this small mass of fibrous cancer had produced the severest symptoms, while in the former case a far greater extent of encephaloid cancer had existed, not only without a single symptom referable to the stomach, but with proof of an unusual degree of activity of the functions of that organ. A third case is also detailed, in which the symptoms resembled those described in the second instance, but the amount of disease was much greater. The body, on examination, presented an appearance of the most extreme emaciation. The heart was of not more than one-third the usual size, and quite without fat. The black pulmonary matter beneath the pleura contrasted very strongly with numerous small white patches on the surface, and entered a little way into the substance of the lungs, which, with the exception of a few earthy concretions, were otherwise healthy. The stomach was reduced to a thickened mass, about the ordinary size of the colon. Internally, it had the appearance of a recently ulcerated surface; the scirrhous degeneration implicating the whole circumference of the organ from the pylorus nearly to the cardiac extremity. Its walls were, on an average, half an inch thick throughout; in some points, full three-quarters of an inch in thickness. There was an extensive deposit of scirrhous tubercles in the omentum, and a few, as noticed in the first case, were scattered about an old hernial sac.

Acne.—Mr. Hunt describes cases of acne, in which he effected a cure by the internal exhibition of arsenic, given in small doses, and its use persevered in for rather a lengthened period. Acne rosacea, he says, is an inveterate form of acne simplex, but differs much from that disease in some particulars. Instead of appearing at the age of adolescence, it belongs rather to the decline of life, commencing at the middle period; and instead of spontaneous disappearing after a time, it usually gets worse and worse, unless checked by medical treatment, till death. The locality of acne rosacea is also peculiar. Instead of appearing on the forehead and chin, its seat and centre is almost invariably the point, or, more rarely, the alæ of the nose, from which it radiates laterally, gradually extending over the cheeks, and affecting the adjacent skin in all directions. The point of the nose first becomes redder than natural, especially after meals, or on exposure to cold or heat; the veins of the part become visible, then pustules form, and slowly progressing through their stages, leave the skin permanently thicker than natural, and puckered with small cicatrices. In its advanced stages, the disease sometimes disfigures the face to a frightful extent; and being, in a few cases, the penalty of dram-drinking, it becomes particularly afflictive to the temperate, in whom, however, it is at least as common. Like other forms of acne, it attacks both sexes, and occasionally occurs as a degeneration of acne indurata of long standing. But the subjects of acne simplex are more generally exempt from acne rosacea. The treatment of acne rosacea has been hitherto unsatisfactory in its general results. Rayner says, the disease "almost always returns after medicines are abandoned, with a rapidity and regularity that induce despair." This is strong language, and from a man of Rayer's experience, most discouraging. Indeed, so general is the impression that it is incurable, that patients rarely seek medical advice for this disease, and still more rarely do regular practitioners undertake the cure in a methodical or persevering manner. Certainly, among the numerous or ill-defined varieties of this disease there are two, the cure of which cannot be reasonably expected. 1. The disease is in some cases hereditary, and, perhaps, likewise congenital. Early in life the nose is slightly affected by the disease, and by degrees, becomes incurably hypertrophied and deformed. Mr. Hunt has more than once known it complicated with an irritable condition of the rectum and with chronic hemorrhoidal affections, the irritation oscillating from one extremity of the intestinal tube to the other. These disorders can be *alleviated* by medical treatment, but there is something originally wrong, which probably can never be rectified. 2. The acne rosacea of the drunkard, connected frequently with visceral disease, is placed by the habits of the patient beyond the control of medical art. With these two exceptions, the varieties of acne rosacea present nothing which justifies an unfavourable prognosis, much less despair. Mr. Hunt relates the case of middle-aged lady, who was affected with this disease, and was apparently cured by arsenic, but neglecting her medicine for a few weeks, induced a relapse, which was again cured by the internal administration of the mineral. A twelvemonth afterwards the disease recurred, but in a milder form, and was soon cured by the mineral. It has not since returned. He regards sycosis as a variety of acne, and also treats it by arsenic, which appears to be his sheet-anchor in skin diseases.

Scotland.

Castor-oil in Affections of the Mucous Membrane of the Bowels.—Dr. Spencer Thomson states, in the *Monthly Journal of Medical Science*, that castor-oil, in the form of emulsion, possesses a really specific power of curing, unassisted, irritation, subacute inflammation, or ulceration of the mucous lining of the bowels. He thinks there are not many cases of infantile or aphthous diarrhœa which are not curable by it alone. In stating this, he alludes to the disease as it occurs during the first year of life, especially among children improperly fed, commencing with sickness, and frequent griped evacuations, varying in colour from greenish-yellow to dark grass-green; these becoming more liquid, and more or less mixed with slimy gelatinous mucus, streaked with blood, or even

at last with a predominance of blood, cachevacua tion being accompanied with pain and tenesmus the mouth dry and aphthous; the anus inflamed the belly tumid and painful; the child becoming more and more feverish, emaciated, and somnolent. In most cases presenting the above symptoms, indicative, according to their severity, of irritation, subacute inflammation, or ulceration, he believes the emulsion of castor-oil with yolk of egg, combined or not with very gentle opiates, will be found sufficient to effect a cure. It is not of course meant that the diet is to be left unregulated, or that assistance is never to be derived from the warm bath, liniments to the belly, or occasional doses of mild mercurials; but these, especially the latter, are only to be regarded as accessories. No mercurial so quickly changes the character of the evacuation as the emulsion, which only requires to be steadily persevered in. The following is the form in which he generally prescribes it for infants:—For an infant of from two to four months old: R. Ol. ricini, ʒi—ʒiss; Vitelli ovi semis., Aq. anethi feniculi, āā ℥j. Ft. emuls. Sumat coch. parv. bis die. To this from two to six drops of laudanum may be added or not; but, of course, this as well as the amount and frequency of the dose, must vary with the case. The mixture is generally taken readily, and even liked. The same preparation is equally useful in that form of intestinal affection which is met with in children of from one to nine years of age, identical with the infantile type before cited, but presenting slightly varied symptoms, such as the tendency of the evacuations to become watery, brown, black, and very offensive; the picking of the lips, nose, &c. In a case of this nature which lately came under his care, the patient, a boy aged three years, lay almost insensible and somnolent. The evacuations, resembling black dirty water, and very offensive, were passed eight or ten times in the twelve hours. Other symptoms of subacute inflammation of the mucous membrane were also present. After the first dose of simple emulsion, there was no motion for thirty-six hours, all the other symptoms being ameliorated. The case, at the date of the report, was progressing favourably. In the diarrhœa and dysenteric affections of adults, the same form of medicine will nearly always effect a cure; it is especially useful in the diarrhœa of typhus, with symptoms of iliac ulceration. In a recent case of subacute hepatitis, in which exhausting diarrhœa was present, accompanied by painfully excoriated tongue, and great abdominal tenderness, the patient was preserved solely by the continued use of the emulsion. The medicinal action of the oil is certainly much modified by its union with the yolk of egg, for the same dose which would act well as an aperient when given alone, when thus combined will scarcely act at all. The preparation generally agrees well with the stomach; but in some cases of irritability of that organ, or where active bilious cholera exist, with frequent vomiting, it is well to delay its administration until the stomach is tranquilised by effervescing salines, hydrocyanic acid, or other usual remedies. In a concluding paragraph Dr Thomson states that the action of croton oil on children is much less marked than it is in the adult. He has frequently found the dose that would purge an adult freely, act as a laxative merely on a child.

Ulceration and Perforation of the Stomach.—Mr. Lawrence narrates, in the *Monthly Journal of Medical Science*, the case of a young woman to whom he was called, and found her labouring under symptoms of peritonitis. She had suffered from dull pain in the region of the stomach for five or six weeks previously; it was aggravated by pressure, and by a full meal. The case terminated fatally The examination of the body was made twelve hours after death. On cutting through the abdominal parietes, they were found perfectly healthy-looking The first puncture of the peritoneal sac gave vent to a considerable quantity of noxious gas, and on enlarging the opening, a large ... of turbid serum and grumous-looking amounting to about two Scotch pints, was nd effused among the contents of the abdomen. peritoneal covering of the bowels presented throughout a preternatural vascularity, and here and there a greyish slaty-looking aspect. There were neither purulent effusion, nor adhesions among the convolutions, nor any spot on these that seemed to have been more especially the seat of morbid action. The omentum was found abnormally thickened and vascular. On examining the stomach, a circular perforation, of the size of a fourpenny piece, was discovered on its anterior and upper aspect, almost in the line of its smaller curvature, and near to the cardiac orifice. On slitting open the organ, its coats, for a considerable way around the ulcerated opening, were found fully three-eighths of an inch in thickness, and the villous tissue highly vascular. The size of the ulcer was much larger in the mucous than in the muscular or peritoneal coat, thus giving it a conical form—its base directed inward, and its apex outward. In the cavity of the stomach was a considerable quantity of the same dark, grumous-looking fluid, which was found effused among the v scera.

Ireland.

New Test for Prussic Acid.—Mr. Austin, jun., in the *Dublin Hospital Gazette*, proposes a new test for prussic acid. The precipi tate of cyanide of silver, say half a grain, obtained in the usual manner, is mixed with a small quantity of oxide of iron and carbonate of potash, and the whole fused together in an iron or platinum capsule. The fused mass is then dissolved in half an ounce of distilled water, filtered, and rendered slightly acid by the addition of a few drops of hydrochloric acid. The liquid thus treated is next divided into two portions, to one of which a few drops of a solution of sulphate of copper is added, hich immediately causes the evolution of the chocolate-brown colour, so characteristic of the ferrocyanide of copper; and to the other a few drops of the muriate tincture of iron, or any persalt of iron, when the solution becomes intensely blue, by the formation of the ferro-cyanide of iron, the ordinary Prussian blue. In Mr. Austin's opinion, these two tests, with the well-known odour of prussic acid, are, independent of all others, sufficient to convince the medical jurist of the presence of free prussic acid. Mr. Austin adduces several arguments to show the superiority of this test over those already known to chemists, both in accuracy and facility of application, by persons not skilled in chemical manipulation. The precipitates above mentioned are very distinctly obtained with half a grain of cyanide of silver.

Idiopathic Gastritis.—Dr. Orpen describes, in the *Dublin Quarterly Journal of Medical Science*, the case of a lady, who was seized with a severe burning pain at the pit of the stomach, which was soon followed by insatiable thirst and vomiting; she had also a short convulsive cough. The epigastric region was tumid and sensitive on pressure, and was the seat of intense pain and soreness. There was great prostration of strength, oppression, restlessness, and palpitation of the heart. The pulse was small and feeble; tongue coated with fur, but red at the point and edges; bowels confined; urine scanty, and severe headache. There was not any pain or tenderness of the umbilical or lower abdominal region. Alcaline draughts were prescribed, and subsequently pills containing calomel, camphor, hyoscyamus, and opium, in small quantities. An enema was also administered, and a sinapism applied to the epigastrium. The symptoms, notwithstanding, became more severe, and the pain and tenderness of the epigastrium increased to such a degree, that the slightest weight could not be borne over that region. There were occasional hiccup, and great restlessness, and agitation. The bdomen was leeched and fomented, and effervescing draughts with laudanum exhibited, but without advantage. Prussic acid was accordingly substituted, but without corresponding benifit. The symptoms continuing very severe, the abdomen was again leeched, and ice exhibited internally, and applied by means of a bladder to the epigastrium. This soon afforded relief; the vomiting ceased, and in the course of a few days the patient became convalescent

A Small Infant.—Dr. Halpin records, in the *Dublin Quarterly Journal of Medical Science*, a case of parturition, in which, after forty-six hours of severe labour, a female child was born, so small that it did not appear to have attained the sixth month, corresponding in this respect to the mother's calculation. Contrary to all expectation it survived, and sucked vigorously. The ossification of the bones of the head was very imperfect; the sutures were broad enough to admit of the middle finger being laid between the bones; the fontanelles were of a correspondingly large size; and she had inguinal hernia on the left side. When four days old, Dr. Halpin weighed her accurately; the actual weight of the child was then two pounds thirteen ounces.

Dec. 14, she being	34 days old, weighed	3lb. 7oz.
27,	47	4lb. 4oz.
Jan. 10,	61	5lb. 4oz.
„ 25,	76	5lb. 12oz.
March 4, „	114 „	8lb. 8oz.

It will be perceived that, in the first thirty days, she gained but ten ounces; in the thirteen that followed she gained thirteen ounces, averaging one ounce per diem.

Land Scurvy Produced by Eating Diseased Potatoes.—Dr. J. McCormack has published, in the *Dublin Hospital Gazette*, the details of a case of disease, which he regards as an instance of land scurvy, and traceable to the use of diseased potatoes. The patient was a factory girl, sixteen years of age, a prey to wretchedness from extreme poverty; her food scanty and unwholesome; her hours of labour excessively protracted, and her work fatiguing. The disease commenced by pain in two of the front teeth, so acute as to preclude sleep at night, and to cause equally intense suffer ing during the day. There was also a sense of chilliness, and disinclination to exert herself in the least. This state continued for a week, when she was unable to leave her bed from excruciating pains in all her joints, and in the small of the back; there was burning heat of the skin, and sleeplessness with delirium for several nights; gums, mouth, and throat so sore as to be unable to take food; sense of weight, accompanied with pain in the region of the heart: palpitation excited by the slightest movement, and general muscular soreness over the whole body. When first seen by Dr. Cormack, the pain in her teeth was excessive; but no appearance of caries; the gums, especially of the lower jaw, were swollen, painful, and spongy, and bled on the slightest touch. even the attempt to swallow caused an oozing of blood. On examining the mouth, he found the gums as described; the teeth loose and extremely painful; the fauces and mouth inflamed and ulcerated in white patches. the tongue flabby and thickly loaded with white fur; the breath horribly fetid; great difficulty in swallowing; pulse 130, small and feeble, muscular pains excruciating; joints swollen and very painful; the skin over the whole body tense, tumefied, and of a preternaturally dark colour; vibices scattered over the limbs; great prostration and despondency; constant involuntary sighing; face and head enormously swollen; countenance pallid and unmeaning; no sleep, from the pains of the joints; the bowels obstinately constipated for several days; the evacuations caused by a dose of senna and salts brought on extreme exhaustion and several fainting fits in rapid succession; the urine was scanty and high coloured; the belly hard and dropsical; heat of skin intense. The two teeth in which the pain commenced were split in two perpendicularly. Dr. M'Cormack says he failed in producing other than mere temporary relief. Another, but a milder case, occurred in Dr. M'Cormack's practice. The patient was a very delicate female, aged nineteen, exposed to cold, hardship, great fatigue, and want of proper nourishment. She was attacked 30th of March with sudden prostration of strength, fainting, acute pain in the abdomen, excruciating muscular and articular pains, especially attacking the neck, shoulders, and back; the skin so sore that the slightest touch caused her to roar out. She was unable even to turn in the bed; bowels confined; urine scanty and high coloured; pulse 130, small and feeble; great heat of skin; tongue loaded; breath fetid; face and head enormously swollen, flushed several times in the day, and pallid afterwards; great despondency, amounting to a certainty of death; headache. She continued in this state till April 4th, when she complained of her teeth being so loose she could not eat; the

mouth sore, gums spongy, and bled on the slightest touch. She is, up to this date, 6th, improving gradually under a generous diet, with bitters, such as quinine, comp. decoct. gentian, &c. The gums are still sore; had not taken one grain of mercury in all her life; the muscular and articular pains still continue, with extreme debility. Dr. M'Cormack then proceeds to give extracts from two papers published in the "Transactions of the Medical and Physical Society of Calcutta," by Drs. Macnab and Ross, showing that a similar disease had prevailed among the sepoys, from bad and insufficient diet. Dr. Macnab, in describing the disease, says the invasion and course of this malady were by no means remarkable for their uniformity; there was a variety in the incipient as well as in the consecutive symptoms. Sometimes one single symptom first manifested itself, and continued to increase steadily for some time before any other supervened (such as ulceration in the gums); at other times, pains and swellings in the extremities were the earliest in the field, and would precede, perhaps by a fortnight, any degeneration in the gums, which would attract notice only after considerable suffering and bodily emaciation; whilst many cases, at the commencement and long after, were extremely ambiguous, and not accompanied, until late in the disease, by any of those marked evidences which distinguished the true nature of the illness. In such cases, the patients complained of excruciating pains in one or more of the extremities, perhaps with little or no swelling, and so closely simulating rheumatism, that in some instances the distinction could not be well established. The following was, perhaps the more regular succession of symptoms. For the first few days the patient felt some soreness in the gums, which might be seen to push up, puffy and congested, between the incisor teeth. There was languor, and perhaps a paroxysm or two of fever, or, at times, regular evening accessions. Day after day the blunt projecting edges of the gums grew more prominent, became more soft, and soon assumed a spongy, hemorrhagic character; the fauces, tongue, and mouth got pallid, and the breath emitted a heavy feculent odour. The pulse increased in frequency throughout the day; irritative fever set in; tormenting pains were developed in the muscular portions (more rarely in the tendinous) of some one or more extremities, such as the leg, arm, or thigh, seldom in more than one member, unless when the cases were of considerable aggravation. These sites became tumefied, exceedingly tense, non-elastic, and over them a colour preternaturally dark. They were more or less diffused, sometimes occupying the whole circumference of the limb, as the leg from the knee to the ankle, which would have a shining polished appearance; vibices occasionally came out in other places, without pain or swelling. In this state the patient's flesh, and strength wasted rapidly—the teeth imbedded in the flabby vegetating gums felt loose, and were unfit for mastication. Horid fetor now proceeded from the mouth, despondency took active possession of the mind. There was no sleep from intense suffering, nor was there any appetite. Blotches frequently occupied the thighs and hips, but occasioned little or no inconvenience. These were of a lighter colour, and of a slightly reddish tinge, or flesh-coloured. Neither the one or the other ever lapsed into ulceration. Sometimes discharges of blood to considerable amount took place from the nose, never from other cavities. From the gums very slight irritation brought blood, in some cases very copiously, at all times to some extent. In proportion as the complaint put on a milder aspect, and became less prevalent, the mouth was much less the seat of disease; in many not at all, the only symptoms being the pains and swelling in the extremities so often mentioned, as prominent symptoms throughout. The secretions in most cases were not materially altered. Seldom was there any constipation, neither were the bowels much relaxed, unless medicine happened to be administered with too free a hand, in which case they might become troublesome. The urine was always high-coloured, and very odorous. The symptoms as described by Dr. Ross bear a near resemblance to those just narrated, and need not be transcribed. The disease previously noticed by Dr. O'Brien as a peculiar form of gastro-enteritis caused by the use of diseased potatoes (see *Medical Times* ante), Dr. M'Cormack regards as a modified form of land scurvy. The only symptom not mentioned by Dr. O'Brien seems to be the swollen, spongy state of the gums—a condition stated by Dr. Macnab to be of less frequent occurrence in the milder form of the disease. Change of air and scene seems to have been the most effectual remedy in treating this disease in India. The remedies that were employed were nitrated vinegar, madar, preparations of iron, mineral acids in conjunction with bitters, such as cinchona, chyraetta, wine, beer; blood-letting in two cases where the patients were robust. The local pains, which constituted a very serious and harassing symptom, were only temporarily alleviated by sinapisms, blisters, fomentations, leeching; washes of all kinds were employed for the mouth without any permanent benefit.

Lectures on some of the more Important Points in Surgery.

Delivered at the Royal Westminster Ophthalmic Hospital, Charing Cross.

BY G. J. GUTHRIE, F.R.S., &c.

LECTURE IV.

Wounds and injuries of the axillary artery; Results of ligature of the subclavian artery; Great fatality of the operation; Mr. Keate's case of ligature of the subclavian, below the clavicle, for axillary aneurism, following a gun-shot wound; Mr. Chamberlaine's case of ligature of the subclavian, below the clavicle, for axillary aneurism, the result of a wound from a cutlass; Case of immediately fatal wound of the axillary artery from a musket-ball; Case of sabre-cut, dividing the pectoral muscle; Case of wound of the axillary artery, and ligature of the injured vessel; Delpech's case of wound and ligature of the brachial artery, followed by secondary hemorrhage from the irritation caused by the ligature d'attente; *ligature of the axillary or subclavian, suppuration under the pectoralis major, and death; M. Galtié's case of ligature of the subclavian above the clavicle, for secondary hemorrhage after amputation at the shoulder-joint; Treatment of hospital gangrene by the actual and potential cautery; Larrey's case of presumed wound of the subclavian artery and vein; recovery without operation; Delpech's case of wound of the carotid; recovery without operation; Elasticity and resistance of arteries to injuries; Larrey's case of sword-wound of the ulnar artery, cured by compression; formation of an aneurism, ligature of the brachial, opening of the aneurismal sac, and ligature of the interosseous artery; Catanoso's case of wound of the axillary artery; ligature of the subclavian below the clavicle; extensive suppuration; enlargement of the wound, and treatment by compression; Montanini's case of ligature of the axillary for false aneurism caused by a wound; Dupuytren's case of ligature of the subclavian, above the clavicle, for an aneurism of the axillary artery following a wound; Lallemand's case of ligature of the subclavian, above the clavicle, for diffused aneurism of the axillary artery following a wound of that vessel; extensive suppuration of the sac; Professor Blasius' case of wound of the arm-pit by a sword; ligature of the subclavian, terminating fatally; Dr. Mouteath's case of ligature of the axillary artery for diffused aneurism, the result of an injury; Messrs. Maunoir's case of ligature of the wounded axillary artery; Desault's case of ligature of the wounded axillary artery; Dr. Segond's case of ligature of the subclavian above the clavicle for a wound of the axillary artery; Dr. Nott's case of ligature of the subclavian, above the clavicle, for secondary hemorrhage following sloughing in the axilla; Mr. White's case of ligature of the subclavian above the clavicle, for a circumscribed aneurism of the axillary artery following a wound of that vessel; Dr. Buchanan's case of ligature of the right subclavian for secondary hemorrhage from the brachial artery; Dr. Gibson's case of ligature of the subclavian, above the clavicle, for an aneurism in the axilla, from external injury without a wound; Dr. Warren's case of ligature of the subclavian, above the clavicle, for rupture of the axillary artery from violence; Injury of arteries from cannon-shot; Mr. Stanley's case of rupture of the inner and middle coats of the brachial artery from external violence; Sir C. Bell's case of lacerated wound of the axillary artery from machinery; Dr. Post's case of ligature of the subclavian, above the clavicle, for secondary hemorrhage after amputation at the shoulder-joint; M. Haspel's case of ligature of the subclavian, below the clavicle, for a wound of the axillary artery; Question of amputation at the shoulder-joint in such cases; Case of wound of the brachial artery, cured by compression; M. Haspel's case of wound of the brachial artery, and ligature of both ends of that vessel at the seat of injury; Mr. Syme's case of rupture of the axillary artery from external violence; formation of a diffused aneurism, followed by amputation at the shoulder joint; Dr. Mackenzie's case of injury of the axillary artery from a wound with a red-hot poker, and ligature of the subclavian above the clavicle; Remarks on the practice of applying a ligature on the subclavian, above the clavicle, for wounds of the axillary artery.*

The axillary artery has not fared better in many instances, than the posterior, tibial, and peroneal arteries. The same dread of dividing muscular fibres has overcome all other considerations, and instead of placing two ligatures on the part of the vessel actually injured, one above, the other below the wound, the subclavian artery has been tied at a distance from the injury, sometimes below, sometimes above the clavicle, oftentimes to the destruction of the patient, and always, even when successful, in defiance of the theory on which such proceeding is founded.

Dr. Norris, of Pennsylvania, has collected and published, in the 10th vol. of the *American Journal of the Medical Sciences*, for 1845, the results of sixty-nine operations performed on the subclavian artery, either above or below the clavicle. Of the sixty-nine cases, thirty six recovered, and thirty-three died. This may be considered as one and one—a result that should cause every surgeon to pause and think again and again before he resorts to an operation, if it can by any possibility be avoided, which may be considered so deadly as to fail in thirty three cases out of sixty-nine. It is his duty to satisfy his mind on running such a risk, that no other operation is likely to be less fatal.

Of the sixty-nine cases, seventeen were done in consequence of wounds of the axillary artery, and of these nine recovered, seven died, and one failed to arrest the bleeding, which was only effected by amputating the arm at the shoulder-joint; eight failures against nine recoveries; eight out of seventeen is in the proportion of thirty-two against thirty six, the average of the whole sixty-nine being thirty-three against thirty-six.

In the seventeen cases collected by Dr. Norris, the operations were done by Messrs. Chamberlaine, Baroni, Galtié, Gibson, Buchanan, Lallemand, Segond, Blasius, Haspel, Catanoso, Montanini, Syme, White, Nott, Hutin, McDougal, and Mott. M. Berard says that in twelve cases he is acquainted with, three only were successful, but this is certainly more than the average mortality.

The object of these remarks is to show that the operation on the subclavian artery is always a fearful one, and the deaths do not seem to depend on the soundness or unsoundness of the artery itself; the mortality being equally great in cases of wounded, as of diseased axillary arteries. It may therefore be safely concluded that the danger lies in the operation, and that it should not be performed when another can be substituted for it, unless that other can be shown to be equally dangerous, when the selection becomes a matter of chance, as far as the life of the patient depends. The operation on the axillary artery itself at the part injured, in all cases of wounds, and in all cases of recent circumscribed or diffused aneurismal swellings, the consequence of wounds, is the substitute which ought in all cases to supersede it. It is an operation founded on principle, which the other is not, and which I

affirm and believe will be found infinitely less deadly.

CASE 55.—The first instance on record of the subclavian artery being included in a ligature, is that in which the late Mr. Keate, surgeon-general to the forces, applied it below the clavicle, in the York Hospital, Chelsea, in a case of axillary aneurism formed after a gunshot wound, of some months' standing, which had burst. Mr. Keate, after dividing the pectoral muscle in the course of its fibres, dipped down twice with a needle and thread, and the second time secured the artery. I was present at the operation, and assisted the late Mr. Carpue in taking care of the man afterwards, who recovered. I was too young to know any thing about the matter, and too much in awe of the surgeon-general to suppose for a moment that any thing he did was wrong. I have however often since thought of the two dips of his needle, and have even ventured to think that the patient was as fortunate in his escape from his doctor as from his disease.

CASE 56.—Mr. Chamberlaine, of Jamaica, placed a ligature on the artery below the clavicle, in 1814, on account of an aneurism which had formed in the axilla, in consequence of a wound received from the point of a cutlass, which bled profusely, and healed in three days, leaving a scarcely perceptible cicatrix. The tumour was as large as an orange; the pulsation very strong; the pain from pressure on the nerves very distressing; there was no œdema of the arm; no elevation of the clavicle. The pulsation in the radial artery was not so firm as in that of the other side, and before the operation was becoming indistinct. The integuments over and above the aneurism were perfectly healthy in appearance. On the 17th of January, eighteen weeks and three days after the accident, a ligature was applied below the clavicle, in the first part of the course of the artery, and the patient recovered.

Remarks.—This was the operation of Anel done below the clavicle, and as the complaint was of eighteen weeks' standing, circumscribed, and with little pulsation in the radial artery, the operation was admissible, especially because an aneurismal sac had formed. I am, however, of opinion that if twenty patients were so operated on, and in twenty more the sac were laid open, and the artery secured above and below the wound, that more would escape with life and limb by the latter than by the former operation.

CASE 57.—A soldier was wounded on the heights of Oporto by a musket-ball, which passed through the pectoral muscle, in the direction of the axillary artery, and went out behind. I saw him just as he expired from loss of blood, and immediately divided the pectoral muscle to see what injury had been done to the artery. The ball had cut it nearly half across, it could neither contract nor retract, and the man had bled to death. If I had been in time to stop the bleeding, and had tied the subclavian artery, above or below the clavicle, the bleeding would have returned, and the man would have been lost, as the wounds of the integuments could not unite, so as to allow of the formation of a spurious circumscribed swelling. The artery could have been secured at the spot wounded with the greatest ease

CASE 58.—A French soldier at Salamanca received a sabre cut vertically and directly across the pectoral muscle, opening into the axilla, and exposing the vessels and nerves. He was afterwards ridden over and taken prisoner by the heavy German cavalry. The wound was always considered a simple one, and healed without difficulty.

CASE 59.—A French soldier, at the battle of Salamanca, received a shot through his chest, and another through the axilla, which bled at the end of several days. I divided the pectoral muscle, and placed two ligatures on the cut artery above the origin of the subscapularis. The hemorrhage was suppressed, but the man died of the injury to the chest.

CASE 60.—Delpech, in the case of a soldier who had been wounded in the south of France, in 1814, tied the brachial artery, as dissection afterwards proved, two inches below the subscapular branch, by an incision carried high up into the arm-pit; and according to the opinions of that day in France, he introduced a ligature under the artery an inch higher up, but which he left loose ready to tighten when necessary. On the ninth day afterwards bleeding took place, and, to his great surprise, he found on trying to tighten the loose ligature that it came through the parts, and had been the cause of ulceration of the artery and of the bleeding. He immediately made an incision two inches and a-half long through the inguments into the wound, in a line between the pectoral and deltoid muscles having then exposed the pectoralis minor, he divided it near its insertion into the coracoid process of the scapula. The axillary or subclavian artery was then seen, and tied, as it is about to pass between the two roots of the median nerve. This operation was so far successful; matter formed however under the great pectoral muscle and neighbouring parts, and the patient sank on the tenth day under his sufferings.

Remarks.—If Delpech had cut through the pectoralis major muscle, he would have left me nothing to suggest, and would have given such free vent to the matter formed under it, and in the axilla, that his patient would, in all probability, have been spared the irritation which caused his death.

CASE 61.—M. Galtié, Delpech's assistant in the Hospital St. Eloi, at Montpellier, tied the subclavian artery above the clavicle, in consequence of hemorrhage taking place from the stump after amputation at the shoulder-joint. The patient died on the third day, exhausted. The opening in the artery was between the ligature on the stump and that on the subclavian, and had been occasioned, it was supposed, by hospital gangrene.

Remarks.—M. Galtié would have given his patient a better chance for life, if he had divided the pectoral muscle, looked the opening in the artery fairly in the face, placed a ligature above and below the wound, and then cauterised all the parts affected by hospital gangrene with a red-hot iron.

When the British wounded had left Toulouse, I visited Montpelier, and was received by M. Delpech, and the physicians and surgeons of the university, and of the Hospital St. Eloi, with the greatest courtesy. Delpech was then in the habit of cauterising all the cases of hospital gangrene with irons at a white heat, with the greatest success. I mentioned to him that we had gained similar good effects from the potential as he had obtained from the actual cautery, and especially from the use of arsenic, potassâ fusâ and the mineral acids in all cases of hospital gangrene and sloughing ulcers. Delpech, in his work on Hospital Gangrene, mentions this fact, and although I do not desire to be considered as the proposer of destructive measures for the cure of sloughing ulcers, I may without impropriety, claim to be the proposer or person who first recommended the use of the nitric and muriatic acids in such complaints. They were used liberally and effectively at Brussels and at Antwerp, and are after all, with the red-hot iron the remedies to be principally depended upon in this complaint, pure or diluted as the exigencies of the case may require.

Hospital gangrene often gave rise to hemorrhage, which led in the Peninsula to securing the vessels, sometimes near, sometimes at a distance from the part affected. I have tied the external iliac, the femoral, popliteal, humeral, radial, ulnar, posterior, and anterior tibial arteries, in consequence of their being opened by this disease. Most of these cases were lost, from the extension of the gangrene to the wound made by the operation, until the local destructive measures alluded to were adopted to arrest its progress. The last case on which I operated at Santander, after the battle of Vitoria, succeeded. It was on the anterior tibial artery.

On my way to England I visited Paris. The Baron Larrey received me with open arms, and took me to his hospital at the Invalides. There he heated his irons, and applied them very vigorously to a large ill-conditioned ulcer on the right hip of a French soldier, who could not refrain from a howl that would have done honour to any gentleman whatsoever. The Baron stopped for a moment, looked in the man's face, and said, "Vous êtes de la garde," and then proceeded with his irons. The soldier uttered not another word.

CASE 62.—Pierre Cadrieux, aged thirty-two, received a wound, in November, 1811, from the point of a sword, which passed in a direction backwards, downwards, and outwards, from immediately above the clavicle, dividing the outer part of the sterno-cleido-mastoideus muscle, and of the scalenus anticus muscle, and opening into or cutting across, as was presumed, the subclavian artery and vein, as they are becoming axillary or passing over the first rib. The bleeding was terrific, and the man fainted and remained as if dead. A compress was applied, and he was brought to the Hospital of Gros Caillou, and placed under the care of Baron Larrey. The next morning he looked like death, and could hardly speak; the wound, which was somewhat more than half an inch long, did not bleed; a swelling had formed above and below the clavicle, pulsating more strongly above. A peculiar thrilling sound could be felt and heard deeply in the direction of the axillary vein; the arm was cold, insensible, and without pulsation in any of its arteries, not even the axillary. The wound was treated by compress and bandage, the arm with warm camphorated fomentations; the patient being supported by wine and good soup, gradually recovered, and as some excitement followed the next day he was bled, and cold was applied to the swelling. Under this careful treatment the wound healed on the eighth day, and the patient gained strength and gradually recovered the use of the arm. On the twentieth day, the aneurismal swelling had disappeared, but the thrill remained, with the pulsations of the vein of the neck, which pulsation never became perceptible in the arm. On the fifty-fifth day some slight pulsations could be felt in the arteries of the arm, and the thrill in the vein had diminished. In 1815 the Baron again saw P. Cadrieux, and found to his astonishment that no pulsation could be distinguished in the axillary, radial, or ulnar artery. A change had taken place in the circulation of the limb, which preserved nevertheless, its warmth and sensibility, although the fingers were drawn forcibly into the hand, from the brachial plexus of nerves having been also injured.

CASE 63.—Delpech, in a nearly similar case of wound, in which he believed the common carotid was wounded near its origin, and which was followed by a terrific hemorrhage which almost destroyed the patient, acted in a similar manner, and with the same successful result.

Remarks.—These two cases show the propriety of that rule I have endeavoured to establish of letting large arteries alone until they bleed and demand attention. There can be little doubt that if Larrey and Delpech had tried to perform operations on these arteries they would have lost their patients. It is time enough to put men's lives in jeopardy when the necessity for doing something is manifest. Formidable operations are not to be done on the speculation that they may be required, and this should never be forgotten, for there are several cases on record in which the main trunk of a limb has been supposed to be divided, when, in fact, trifling branches only have been injured.

An artery possesses an elastic and resisting power which enables it to yield in a great degree to an opposing force without being torn, and to suffer a degree of contusion which would lead to sloughing in other parts with little comparative injury.

I published the case of Captain Flack in my work on Gunshot Wounds, page 330, in which several inches of the femoral artery were laid bare by a cannon shot, and were seen for three weeks pulsating in the usual manner, until gradually covered over by granulations. In this case the artery maintained its life and functions unimpaired.

At the battle of Albuhera, Captain Gibbons, of the fusiliers, was wounded by a musket ball, which entered immediately below the clavicle, and passed out behind, so directly in the situation of the axillary artery, that it was supposed it must be injured. Great inflammation followed in the chest, and his life was saved with difficulty. He died of phthisis in 1829; and on examining him particularly, I found that the artery was obliterated at the part where the ball had passed by the side of it. I have seen, however, many instances in which no such event followed. The late General Sir Lowry Cole, was wounded when advancing with the 4th division of infantry to attack the French centre at the battle of Salamanca. The ball passed under the clavicle, injured the first rib close to the artery, and passed out behind, without implicating the

artery or giving rise to any inconvenience, further than a diminution of the force and size of the artery at the wrist when compared with the other. At the first siege of Badajos, two officers of the 40th regiment met with injuries nearly similar; and I have seen the subclavian artery as well as the carotid fairly divided; but then death immediately ensued. The fact of arteries yielding a passage to a ball, and re covering themselves and their situation without rupture or sloughing, is well shown in case No. 24, of Turnbull, and is I believe sufficiently established to require no further confirmation.

CASE 64.—L. B., twenty years of age. In Sept., 1811, was wounded by the point of a sword in the right arm, which opened the ulnar artery. The bleeding was arrested by compression, and the wound healed in twenty days. Shortly afterwards a small tumour of an ovoid form appeared under the cicatrix of the wound, which, in the course of a few months, attained the size of a man's first. Larrey tied the brachial artery in the arm above the tumour, and afterwards laid open the aneurismal sac, which was full of layers of fibrous coagula he had some difficulty in detaching; he then sought for the upper and lower ends of the artery, which he thought had been divided and separated by the sword; this had not however happened, but the artery at the wounded part had become dilated, the portion immediately above being funnel-shaped or dilated in that form, the lower end being on the other hand, obliterated; between these two points the inter-osseous artery entered the sac, and bled so freely as to require a ligature being passed around it underneath the sac. The ligature on the brachial artery came away on the ninth day, that on the interosseous artery on the eleventh, and the patient was cured in six weeks.

Remarks.—If the Baron had been contented with his first ligature, his patient would have been well in half the time, and with less than half the suffering. By opening the sac he placed an aneurism of some months' standing in the state of a wounded artery, and had to tie a vessel with a good deal of difficulty, which never should have been exposed.

CASE 65.—Catanoso, of Messina, in September, 1835, was called to a man with a wound in the arm-pit, which oozed blood frequently until the fourteenth day, when an alarming hemorrhage caused him to place a ligature on the artery, below the clavicle, which he found it very difficult to do. The wound did not heal by the first intention, but suppurated, and discharged a quantity of sanious and offensive pus mingled with coagulated blood. It was therefore enlarged to give free vent to the discharge. On the nineteenth day after the operation, arterial hemorrhage took place. The clots being removed, the hollow whence the blood proceeded was filled with resin and charcoal, gum arabic, retained by compresses and a tight bandage. The hemorrhage did not return, but the cure took some months to complete.

Remarks.—If the operator had divided the an terior fold of the arm-pit by a perpendicular incision, and placed one ligature above and another below the wound in the artery, his patient would not have had in all probability secondary hemorrhage, and would have been cured in half the time, and with much less risk.

CASE 66.—Montanini, of Naples, tied the axillary artery below the clavicle, sixteen days after the accident, in a case of wound which healed early, and allowed an aneurismal tumour to form the size of the fist. Six days afterwards the tumour burst, and about five ounces of coagula were discharged. The sac suppurated, but no bleeding took place. An abscess formed under the pectoral muscle, requiring to be opened. The patient was cured in thirty-six days.

Remarks.—The inflammation of the sac which led to its rupture on the sixth day, closed the axillary artery below in all probability, or the patient would have bled to death, unless another operation had been performed to tie it also.

CASE 67.—C. Chevalier, aged thirty-seven, was wounded, in 1811, in Spain, by a thrust with a sword on the back of the shoulder, which caused him to faint after a great loss of blood. The wound healed in three weeks. Two months afterwards he perceived a small tumour in the axilla, about the size of a nut, and pulsating. Two years afterwards it was as large as a hen's egg, and after some laborious exertions it rapidly attained the size of a child's head. M. Dupuytren tied the artery above the clavicle, between the two scaleni muscles, the anterior of which was divided; the man escaped, and at the end of several months resumed his occupation of a joiner, and enjoyed good health for three years. The tumour did not entirely disappear, for after a great exertion, inflammation and pain came on in the axilla, and he applied at the Hotel Dieu again in 1822. At the end of a fortnight it suppurated, burst, and discharged a large quantity of matter, having the colour and consistence of pounded raisins. The opening was enlarged, the sac injected, and he left the hospital, cured, in three months.

Remarks.—This was an aneurism formed after the manner supposed in cases 55 and 56. Being of long standing, the ligature of the subclavian above the clavicle was admissible, but there can be no doubt that this man would have run less risk if the sac had been laid open when of the size of a hen's egg.

CASE 68.—Lallemand of Montpellier (*Archives Generales de Medecine* vol. vii.), was called to a young man who was wounded by the point of a sword through the middle of the anterior fold of the arm-pit, and lost a good deal of blood at the time; but as the small wound became obstructed, the blood only oozed out; a large effusion, however, took place into the armpit, and into the cellular membrane of the chest, arm, and neck. M. Lallemand with great difficulty tied the subclavian artery above the clavicle. On the twelfth day the ligature separated, but the diffused aneurismal tumour became large and more painful; fluctuation being manifest, a puncture was made into it, and an enormous quantity of chocolate coloured matter was evacuated, together with many large black lumps of coagulated blood. The day after another swelling required another puncture, for the evacuation of a further quantity of fetid pus, with sloughing cellular membrane, &c. A third abscess formed, and required another puncture, followed by similar results. A month after the operation the pulse returned in the radial artery, eight days after in the ulnar, and the patient ultimately recovered.

Remarks.—If an incision had been made at first, through the anterior fold of the arm-pit, the coagulated blood would have been readily evacuated, the wounded artery would have been tied, and the patient cured without difficulty. If the collateral circulation had been early established, this operation would have been necessary to stop the bleeding which would have taken place. This man had a lucky escape from his accident and his operation.

CASE 69.—It is stated in vol. xxx of the *Med. Chir. Review* that a young man was brought to Professor Blasius, of Hallé, with a wound through the posterior fold of the arm-pit from a sword; he bled profusely and on several occasions. On the twentieth day after the accident, Professor Blasius tied the subclavian below the clavicle, and the patient died from exhaustion two days after. On dissection the axillary and vein were found uninjured; the bleeding had taken place from the circumflexa humeri posterior and circumflexa scapulæ arteries. Dr. Blasius condemned in severe terms the negligence of not laying bare the artery or arteries wounded, and applying a ligature to them.

Remarks.—It is plain that if these arteries are of any use in the collateral circulation, bleeding must be renewed by them, after the subclavian has been tied above their origin, unless they should be accidentally closed in the interval. I need not add to the forcible criticism of Blasius, which is unanswerable. In this, as well as in Case 67, the posterior fold of the arm-pit might have required to be divided instead of the anterior.

CASE 70.—Dr. Monteath, of Glasgow, was called to a gentleman on the 20th of September, 1813, whose right arm had been run over by a heavy coach, about its middle, and bruised from the shoulder to the wrist without lacerating the skin. Great inflammation ensued, followed by suppuration, the matter being evacuated by an incision over the biceps muscle, twelve days after the accident. This was followed by great sloughing of the integuments, and on the twentieth day by hemorrhage inducing syncope. Hemorrhage again took place, and some operation to arrest it was necessary. The gangrene had extended close to the boundaries of the axilla, and the axillary artery was, therefore, secured by ligature as high up as it could be got at by an incision at the arm-pit, under the anterior fold made by the pectoral muscle, and, as Dr. Monteath believes, above the origin of the subscapularis and circumflex arteries. The patient recovered with an arm, after a time, "in all respects perfect."

The Messrs. Maunoir of Geneva, performed nearly a similar operation, after a sword-wound, with success. Desault, Langenbeck, and Roux, have each recommended the division of the pectoral muscle for this purpose, and if Desault had been better acquainted with the management of the ligature, success would have attended his efforts, and he would have left me nothing to propose, but to follow the example he had set in 1795, in the following case.

CASE 71.—The point of a sword passed through the pectoral muscle, an inch above its lower edge; a great quantity of blood was lost, and a large swelling formed in the axilla, between the folds of the arm-pit. Seven days afterwards the man was admitted into the Hôtel Dieu. An incision was made in the course of the axillary artery, commencing below the clavicle. The two lower thirds of the pectoral muscle were divided, and the coagulated blood removed from the axilla, so as to expose the artery, veins, and nerves. So far the proceeding of Desault was to be applauded. He then included all the vessels and nerves in one mass by a temporary ligature. The artery was then separated, and tied separately immediately above the origin of the circumflex and subscapular arteries. The temporary ligature was then loosened, but was not removed. No more ligatures were then applied below the wound in the artery. The man died six days afterwards of mortification.

Remarks.—If in this case Desault had placed two ligatures on the artery, one above and the other below the wound in it, instead of four, without fear of being unable to command the bleeding, his patient would, in all probability, have recovered.

CASE 72.—Dr. Segond, in French Guiana, in April, 1834, was called to a wound of the axillary artery in a negress, which took place by a fall in February. The fourth or fifth day after the accident she lost a great quantity of blood; at the end of a month she seemed nearly well, with the exception of a small abscess, from which a little bloody discharge took place, and in which an aneurismal tumour had formed. The subclavian above the clavicle was tied, and the patient recovered very fortunately.

CASE 73.—Dr. Nott, of Alabama, U. S., was sent for to C. Clausel, aged thirty, shot through the wrist and axilla by small shot on the 27th of August. The wrist was amputated. A slough formed in the axilla. On the twelfth day hemorrhage took place to the extent of two pints, returned on the thirteenth, and again on the sixteenth; it was arrested by compression. On the eighteenth day the slough separated, leaving a large cavity in which the artery could not be felt. By the middle of October the cavity had filled up, and the ulcer had nearly healed, when an aneurismal tumour began to form and gradually extended up to the clavicle. On the 29th of November a ligature was placed on the artery above the clavicle. On the thirty-first day this came away, having been so tightly tied that an ordinary sized pea could hardly be passed through the noose after it came away. On the fortieth the wound had healed, but the pulsation which had returned on the second day after the operation was still strong and the *purr* distinct. These had a little diminished in five months, and the patient was found to be cured two years afterwards.

CASE 74.—Mr. White, of the U. S., tied the subclavian above the clavicle, in September, 1838, for a wound of the axillary artery, which had formed a circumscribed aneurism likely to burst. The operation succeeded.

CASE 75.—Dr. Buchanan relates a case in the third volume of the *Glasgow Medical Journal*, in 1830, page 283, in which he tied the subclavian artery of the right side in consequence of hemor-

rhage from the brachial artery, the result of th separation of mortified parts after a severe injury. The man died five days after the operation. Th post-mortem report says, after the parts had bee dissected, and the scalenus anticus muscle had been cut and turned aside, "the subclavian artery wa well seen with the ligature firmly tied round it, and a hard clot of blood perceptible on its cardiac side The clavicle was now removed, and the axillar artery traced under the pectoralis, onwards to its termination in the stump, during which transit it seemed quite healthy, till about an inch below the axilla, when it assumed a soft, greenish appearance and no clot could be discovered on the distal side o the ligature. The muscles surrounding the shoulder joint were soft, green, and matted together, and a large collection of fetid pus extended from the slough below the axilla, to the under surface of the pectoralis major and minor, the whole substance of which last was in the same gangrenous state as the muscle of the shoulder-joint.

Remarks.—Dr. Buchanan justly attributes the immediate cause of death to mortification of the extremity, but he does not seem to consider that its continuance and extension were at least maintained and encouraged, if not rendered inevitably destructive, by his having *cut off* the supply of blood around the shoulder, by tying the subclavian artery above the clavicle. This he did, because he supposed the operation of tying the artery under the pectoralis major and minor to be an operation which had never been done, and says, "Further, I am of opinion it never ought to be had recourse to." Thi was Dr Buchanan's error. The very simple operation of dividing the integuments and pectoralis major muscle from a little below the clavicle into the axilla would have exposed the artery, which it will be seen from the dissection report was quite healthy, even for an inch below the axilla. Thi incision was also necessary, if for the purpose only of giving a free vent to the matter collected under the pectoralis major and minor and around the shoulder-joint. It would have tended to arrest the sloughing process, and the arm, having the advantage of the collateral branches which were cut off by tying the subclavian, might not have been lost. It is possible the man might not have died.

I have stated that the principal trunk of an artery may be injured by internal and by external violence without any wound of the integuments, of which the following cases are examples :—

CASE 76.—Dr. Gibson, of Pensylvannia, after reducing an old dislocation of the head of the humerus of ten weeks' standing, on 15th of March, 1828, which occupied one hour and a half, discovered the next day that an aneurismal tumour had formed in the axilla; and on the 17th he tied the subclavian artery above the clavicle; mortification of the hand and arm followed, and the man died on the 23rd. On dissection it was found that a small aneurismal sac had been ruptured, and which it was supposed might have existed from the period of the accident.

CASE 77 James A , aged about thirty, on the evening of December 23rd, 1843, while in a state of intoxication, slipped on ice, fell, and struck his left shoulder against the kerb-stone of the side walk. Violent efforts were made to reduce the dislocation, but in what manner the patient could not tell, excepting that he thought one person placed his foot with a boot on, in the axilla. He was sent to the hospital, and on the next day was seen by Dr. Warren, who found the left arm and shoulder much swollen. Leeches and cold applications were employed, and on the following day the swelling was so much reduced as to enable him to decide that no dislocation existed. During the night of the third day following (December 28th), the patient was seized with a violent fit of coughing, during which he felt something give way in his shoulder. The next morn the shoulder and arm were very much discoloured and enlarged; the arm was painful, and the pat [illegible] prostrated. On the 30th it was discovered that the man had no pulse in his left wrist, or in any [illegible] of the arm, and he had also lost both feeling [illegible] motion in the extremity. The swelling incr[illegible] until it became enormous, the [illegible] in the axilla. A vesication was [illegible] on the back of the forearm. January 27th, 1844, an abscess was found to be forming in the axilla. In seven days it pointed, but did not ope till February 4th, when it discharged a coagulum, and about a pint of fluid dark-coloured blood. Three days subsequently, at six o'clock in the morning, a sudden gush took place from the wound, b which the bed was inundated, the mattresses soaked, and the blood poured upon the floor. Exhausted and almost lifeless, he sunk into a state syncope, and the hemorrhage ceased. As he was too low to undergo any operation, it was agree that if he lived till the next day, the subclavian should, if possible, be tied. By the next morning he had much revived. At ten o'clock he took eighty drops of the tincture of opium, and at eleven was carried into the operating theatre.

A great difficulty presented itself in the outset o the operation, the swelling of the shoulder, the tumor in the axilla, and the natural shortness of the neck almost obliterating the space between th shoulder and lower jaw. Dr. Warren, after minutely detailing the steps of the operation, state that the aneurism-needle was passed under the first dorsal nerve, which was mistaken for the artery. The wound was too deep, too narrow, and consequently too dark, to permit the artery to be visible The anterior scalenus was partially visible, and, passing the forefinger of the hand to the edge o this, a good portion of the muscle was divided by the probe-pointed bistoury, introduced upon th finger. The subclavian artery then became quite sensible to the touch, and slightly distinguishable by the eye. A long aneurism-needle was passe under the artery, and at this moment a sligh whistling was heard, and the author was satisfie that some air had entered the thorax. The ligatur was tied, and the wound closed.

The patient improved after the operation. On February 22nd, the thirteenth day, the ligature wa removed. On the 29th, a stream of blood was seen to issue from the unclosed part of the wound; th blood lost amounted to about a pint, did not issue per saltum, and was of a venous colour. The hemorrhage was arrested by pressure. At the commencement of March, he had an attack of pneumonia confined to the lower lobe of the left lung, and also a second attack about the 1st of May. By the 1st of October, the swelling had disappeared from th arm, and motion had returned in the shoulder oint. The large excavation in the axilla was reduced to a fistulous tube. On February 4th, thre hundred and sixty-one days after the operation, Dr. Warren was able, for the first time, to detect a dis nct pulsation in the radial artery, and subsequently one of an indistinct character in the ulnar and brachial. The patient, June 15th, had nearly covered. There were still fistulous openings in he neck and axilla. Sensation and motion were slowly improving.

Dr. Warren remarks, that the cause of the rupture of the subclavian artery in this case is involved n some obscurity. The probability seems to b hat great violence was employed in the attempt to educe the bone, and that the arteries and nerves were contused by strong pressure of the operator's oot, combined with the forcible extension of the rm. The vessel did not rupture immediately, ecause its coats were contused, and not torn sunder, but a separation of the contused parts ook place, in consequence of the violent efforts of coughing, on the fifth day after the accident.

Remarks.—I have had the pleasure of making the acquaintance of Drs. Gibson and Warren, of whose private character and professional attainments it is impossible for me to think too highly. They are universally acknowledged. I am therefore the more willing to express my dissent from the principle on which they acted in these instances. In Dr. Gibson's case the mortification which ensued fter the operation might not have occurred if the aneurismal tumour had been opened, and the artery had been secured above and below the part injured; for I consider the mischief to have arisen from an an injury, and not from disease of the artery. If Dr Warren had cut across the integuments and the pectoral muscle in his case, and laid open the tumor in the whole of its extent, he would have been able to see the torn or even ulcerated part of the artery whence the bleeding came; for as the vessel was injured by the heel of the boot of the person who reduced the dislocation, provided there had been one, the artery must have been injured in the third or last part of its course before it becomes humeral, and the patient would in all probability have been perfectly well in two months, even if it should have been subsequently necessary to have placed a ligature on the lower end of the divided vessel, that is, the upper end of the humeral artery. The man nearly lost his life on the 29th of February from hemorrhage of a venous character, caused by the operation on the subclavian artery, which danger need not have been incurred, and he ran the risk the whole time of an arterial bleeding being renewed from the cavity in the axilla. When it shall be shown that the operation of dividing the pectoral muscle, and of tying the axillary artery at, under, or above the pectoralis minor muscle is more dangerous than tying the subclavian artery above the clavicle, I will yield my opinion that the subclavian artery should not be tied above the clavicle; but in the meantime, I may be permitted, without any great presumption, to say that this operation will be found to be at least three times more deadly in its average result than the other.

When a cannon shot strikes a limb, and bruises it most severely, without carrying away any part, constituting a sort of injury which I have explained, page 128 of my work on Gunshot Wounds, the great artery or arteries may be ruptured, not only in one spot, but the internal coat may be injured in several. I have given an account of one particular case, in which on dissection it was found that the posterior tibial and fibular arteries were torn across, and the popliteal artery, two inches higher up was closed by coagulable lymph thrown out from a rupture of the internal coat of the artery at this part. The limb mortified. These cases are supposed erroneously to have occurred from the wind of a cannon ball.

CASE 78.—A boy, twelve years of age, had a waggon wheel pass over his arm and thigh. In the thigh there was a compound fracture. In the arm there were no other outward marks of injury than two or three small wounds, penetrating only the skin; but the arm throughout was cold and pulseless. In the axilla the pulsations of the artery could be felt, but nowhere below it. On the morning after the occurrence of the injury, the boy became delirious, and in the evening of this day he died.

Mr. Stanley on examining the arm found the biceps torn across its middle, and in the same situation the trunks of the vessels and nerves were all separated from each other by the laceration of their connecting cellular tissue. The brachial artery, for about two inches of its extent, appeared to be remarkably small, and on slitting it open, its inner and middle coats in the middle of the arm were found to be completely divided, its outer coat being entire. For nearly two inches above the laceration of the inner and middle coats, the canal of the artery was extremely contracted, and filled by a slender solid coagulum.

Mr. Arnott has noticed a nearly similar degree of mischief as occurring after the passage of a wheel over the limb, and this accident has been observed by others, and particularly by Mr. Turner, in the Transactions of the Medico-Chirurgical Society of Edinburgh.

Wounds of the axillary artery have been treated not only by ligature of the subclavian artery, but also by amputation of the extremity at the shoulder-joint—a mode of proceeding the expediency of which deserves consideration.

CASE 79.—Sir C. Bell says in his Commentary on John Bell's Surgery, vol. i, p. 369, "a girl had her arm torn off near the shoulder by machinery. There was no bleeding, nor could the trunk of the artery be seen. As the arm had been almost fairly amputated by the machine, it was unnecessary to do more than make the edges of the wound even, and bring them together. As the axillary artery had not been tied, the patient was carefully watched. In the course of a few days hemorrhage did come on, and the surgeon very properly tied the artery below the clavicle. The bleeding from the stump immediately stopped, and everything went on well for several days; the stump became clean, and was granulating, when a second violent hemorrhage took place from it. The surgeon did not reach the hospital until the patient had lost a considerable quan

tity of blood. He immediately tore open the stump, which was already partly united, and now he saw the blood issuing from the main artery. He secured it; but the patient sunk next day. On dissection, and by injecting the vessels, it was shown that the artery, where it had been tied below the clavicle, was obliterated, and that the blood had passed round by the supra-scapular branch of the inferior thyroid, from the portion of the subclavian artery above the ligature into the part below."

The surgeon in this case performed a very dangerous operation in a very admirable manner, and according to the principles he had been taught. Nevertheless, it was done contrary to every principle of good surgery, and, as far as I can see, for no other reason than for the purpose of avoiding a few fibres of the pectoral muscle.

In the first place, an operation, confessedly a very dangerous one, was done when it was in no way necessary, and which proved perfectly useless, a second requiring to be performed afterwards, of a very simple kind, and which was the one which ought to have been done at first, namely, searching for the bleeding end of the artery, and tying it. A life was here lost for want of a knowledge of principles. The operation failed, not for want of anatomical knowledge or dexterity, but from misapplication.

CASE 80.—Dr. Post, of New York, in 1845, tied the subclavian artery above the clavicle, in consequence of hemorrhage from the stump after amputation at the shoulder-joint. This patient recovered, whilst Dr. Gibson's case died of mortification, and Mr. Bell's from hemorrhage. The artery, in my opinion, ought to have been secured in Dr. Post's case by an incision through the pectoral muscle in the course of the vessel.

CASE 81.—Bigneux, of the 1st battalion of Artificers, was wounded in the arm pit in a duel, on the 4th February, 1835, at Metz, and suffered a considerable loss of blood. The anterior fold of the arm-pit was divided, and on examining the wound, a jet of blood, as large as the finger, darted from it. M. Haspel laid bare the subclavian artery by a separate operation below the clavicle, and secured it by ligature. The hand and forearm mortified; the limb was amputated; in a few days the man died. On dissection, a considerable effusion of blood which had formed into large clots was found in the cellular membrane at the back of the shoulder, and which M. Haspel supposes would have led to such irritation and suppuration, as might have placed the patient in great danger if he had survived. The ligature was found on the artery an inch and a half above the part where it was divided.

Remarks.—M. Haspel offers for the consideration of surgeons the question, whether it would not have been better to have amputated the arm at the shoulder in the first instance ? I am of opinion that if he had enlarged the wound upwards, placed a ligature on the artery, immediately above where it was divided, and another in a similar manner on the lower end of it, this patient would have preserved his arm and his life. The clots of blood would have been discharged through the enlarged and dependant wound he had made, the patient being able in such cases to maintain an inclined if not an erect position for the greater part of each twenty-four hours.

CASE 82.—M. Renneville, captain of cuirassiers, was wounded in a duel by a sword, which cut through the inside of the upper part of the arm, and gave rise to a considerable hemorrhage, which was stopped by compression. The radial artery ceased to pulsate until the third day; the compression being continued in the course of the upper part of the artery, the wound healed, and the patient recovered, the brachial artery being obliterated to the space of about two inches. This case is a counterpart to No. 2.

CASE 83.—Delahaie, sergeant 33rd infantry, was wounded by a sword, which divided the brachial artery at the upper part of the arm, close to the armpit. The artery was divided in the wound, together with the median nerve, and the lower end of the vessel was readily tied; the upper end had retracted, and could only be found after enlarging the upper part of the wound, when a ligature was applied, which came away on the twelfth day. The patient recovered.

Remarks.—M. Haspel, it would appear, had taken warning by what had happened in 1835, to Bigneux, and adopted a different course in 1839, a proceeding worthy of imitation, and highly to his honour.

CASE 84.—On the 23rd of September Mr. A., twenty-three years of age, was thrown out of a gig upon the road with great violence, and lighted on his left shoulder. It was at first thought that the humerus had been dislocated downwards; on more careful examination, it appeared that the bone was in its proper place, and that the hard tumour in the axilla depended on effusion of blood. The patien was kept quiet in bed, with cooling lotions applied to the injured part. For a day or two the swelling increased, extending down the arm, and the side of the body, and attended with discoloration of the skin. On the tenth day after the accident, a sensation of gushing was felt in the armpit, and the pain and tension suddenly became as great as ever. Leeches were applied, and the case again proceeded favourably for eight days, when another gush took place. Attacks of this kind then became more frequent, and at length occurred almost daily. They were always relieved by leeches, of which about three hundred had been applied. The arm was now enormously swelled by œdematous effusion, which extended to the points of the finger. A large fluctuating tumour occupied the axilla, and distended the pectoral muscle. There was no pulse at the wrist, and not the slightest movement or sound could be perceived in the swelling. The patient, worn out by pain, loss of blood, want of sleep, low diet, and apprehension, was reduced to a state of extreme weakness. In these circumstances it seemed difficult to determine whether there was an axillary aneurism or merely a bloody effusion. The gushing sensation, and absence of pulse at the wrist were in favour of the former view, while the complete absence of pulsation and aneurismal bruit in the tumour, from its commencement and during the whole period of its existence, could hardly be accounted for, except by the latter explanation. The case being thus doubtful, and as pressure had not been tried, it did not appear prudent to resort to any operation, until the effect of careful bandaging had been ascertained. A flannel roller was accordingly applied from the fingers to the shoulder and round the chest. He derived great comfort from the bandage: the swelling of the arm was considerably reduced, and there had been no return of the gushing sensation. He continued in this satisfactory state for three days, but on the morning of the 24th, severe pain was felt in the most prominent part of the swelling. This corresponded with the hollow of the axilla, and formed a round prominent tumour, of a dark-red colour, apparently about to break. An opening was made to the extent of half an inch, when a small clot of blood only was squeezed out, and a piece of lint was laid loosely upon the wound Four hours afterwards the piece of lint was observed to be wet with arterial blood, a jet of which immediately followed. By means of a pin thrust through the lips of the wound, and a ligature tied round it, further hemorrhage was prevented for the time. The subclavian artery was now tied with a single silk ligature. The patient passed the remainder of the day tranquilly, and in the forenoon of the next seemed to be going on well. But at two o'clock, p. m., two or three ounces of blood escaped from the wound in the axilla, and a compress of lint was then secured over it by means of a spica bandage. At seven next morning, as the bleeding returned to somewhat larger extent, the surgeon stuffed the orifice with lint. At eleven, a. m., it was thought right to lay open the cavity, turn out all the clots that could be reached, and apply graduated compresses. When the artery was thus exposed it bled freely, but not with such force as to resist the pressure of the lint. In half an hour afterwards, however, the hemorrhage recurred, and as the temperature of the arm was then distinctly lower than natural, the only remaining resource seemed to be amputation at the shoulder-joint, which was done. The patient, for several hours after the operation, threatened to sink under this final act of his trials. He complained of nausea, and was deadly pale; his face was covered with cold perspiration; and his pulse could hardly be felt. Small quantities of wine were given to him frequently, and in the evening he revived, feeling warm and comparatively comfortable; the pulse became firm and could be counted—160. Next day it was 140; the day following, 120; and so on until it fell to the natural state. In other respects the improvement was equally progressive, and before the end of a week there was no room for anxiety, except on account of the ligature above the clavicle. It was longer of separating than usual, but probably lay loose for some time before it came away, owing to the patient's extreme aversion to let it be touched. His recovery was complete both in regard to the wound and the general health. The points in this case most deserving of attention are:—1. The way in which the artery was ruptured; 2. The absence of pulsation and aneurismal bruit in the tumour; 3. The inefficacy of tying the arterial trunk at a distance from the rupture, and with the intervention of branches; 4. The success of amputation in very desperate circumstances. Whether pulsation was prevented by the artery being torn entirely across, and whether ligature of the subclavian would have proved effectual if not preceded by puncture of the tumour, are questions which the writer of the case leaves to the consideration of the reader.

Remarks.—This case gives support to the fact I believe to be sufficiently established, that the bruit, hiss, or aneurismal sound which may be heard by applying the ear to the part when an artery of size is wounded, is not always distinguishable through a quantity of blood which has been suddenly effused and has coagulated, whether from a wounded artery or from the rupture of an aneurismal sac, although it is distinct as long as the blood remains fluid Pulsation is equally indistinct when the blood effused is coagulated, although the swelling may be elevated like any other tumour by the proximity of the artery, particularly if the main trunk is uninjured, and the blood has been poured out by a branch. The swelling was opened simply to prevent its bursting disadvantageously, and if the operator, on finding that arterial blood flowed in such quantity as to render further proceedings necessary, had laid open the tumour in all its extent, as he was obliged to do two days afterwards, and had secured the artery above and below the wound in it, the patient would not have lost his arm, nor have run so much risk of his life, as the operation on the left subclavian artery always occasions.

CASE 85.—Dr. Mackenzie was called, on the 5th of November, 1845, to a man who had fallen, with the whole of his weight, on a red-hot poker, the point of which entered the right axilla, immediately below the tendon of the pectoralis major, and seriously burned all the parts it touched. Eight days afterwards, a large eschar separated, followed by a copious flow of blood, which was arrested by pressure. The continuance of this by means of a graduated compress and bandage, evidently did mischief to the surrounding parts, and as the bleeding recurred, from time to time in spite of it, something more was clearly necessary. Three courses were, it was thought, open to the surgeon: one to cut through the pectoral muscle, and to place a ligature on the artery, above and below the part injured; the second to tie the subclavian artery above the clavicle, and if this should not succeed, in consequence of the collateral circulation re-establishing the hemorrhage, the arm was to be amputated at the shoulder-joint, under the advice of Mr. Syme as the third and last resource; because as Dr. Mackenzie says, "the vessel would probably have been divided in the incisions, above the injured point;" and the patient was in a state by no means unfavorable for the performance of such an operation. Again, the anastomosis existing between the branches of the axillary and subclavian arteries, rendered the propriety of trusting to a ligature of the latter vessel, as a means of arresting the hemorrhage, questionable. The subclavian was tied above the clavicle, the bleeding did not recur, and the patient recovered.

Remarks.—These four cases may be properly considered together. Four men of the greatest ability and eminence in their profession, tied the subclavian artery on account of a wound of the axillary artery; and it is admitted that in all four cases it was done above the origin of the subscapular and circumflex branches. These vessels are acknowledged to be essentially necessary for the pre-

servation of the life of the limb, the blood being brought round from the neck and shoulder by their means into the principal trunk, the canal of which was obstructed above by the ligature placed upon it. When blood had been so brought round into the main trunk above the hole in it, it is fair to inquire what was to prevent its flowing through it, and renewing the bleeding? The answer must be, nothing, unless a coagulum had accidentally formed to stop up the hole, which a very slight impulse or motion of the patient might remove, as it has been shown has taken place in many cases that have been related; or that a healthy inflammation had taken place in the artery, and had clogged its canal by the usual processes of effusion, and consequent obliteration, both being matters of mere chance. In Sir C. Bell's, case, No. 79, the blood did so come round the shoulder, did renew the bleeding, and thus destroyed the patient. In Mr. Stanley's case, No. 49, one inch and a-half, at most, of distance between two ligatures on the posterior tibial artery did the same thing; no reliance can, therefore, be placed on any presumption or idea that the collateral circulation will not always do so, and that the patient will not always be destroyed in a similar manner. In case No. 81, that of M. Haspel, the subclavian artery was tied for a wound of the axillary artery through the anterior fold of the arm-pit; the arm mortified, the limb was amputated, and the man died. The collateral branches failed to restore the circulation, and the bleeding was not therefore renewed; its failure caused the limb to mortify, and the man suffered an unnecessary painful operation and died. Death in either way. In case No 81 the subclavian artery was tied for a diffused but bleeding aneurismal swelling in the axilla after a wound. The collateral branches restored the circulation, and the bleeding was renewed. The wound was now laid open, the surgeon saw the artery bleeding freely, and concluded his operation by amputating the arm at the shoulder-joint, instead of placing two ligatures on the bleeding vessel, which might have saved the arm. The patient slowly recovered.

A Course of Lectures on Practical Midwifery.

Delivered this Session at St. Bartholomew's Hospital, and revised specially for the Medical Times,

By EDWARD RIGBY, M.D.,

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery to St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

PREMATURE EXPULSION OF THE OVUM—NATURAL LABOUR.

(Continued from page 14.)

GENTLEMEN,—I told you at our last meeting that if the flooding in cases of threatening abortion be profuse, you will have little hope of saving the embryo, and I also explained the reason of this to you on the same occasion. I shall now tell you the treatment to be pursued in cases of severe hemorrhage I must, however, first notice that the bleeding in these cases has been recently supposed to proceed rather from the venous mouths of the detached portion of placental surface than from the uterine vessels.

I my last lecture I told you that we must divide the treatment of premature expulsion under two heads—the attempt to save the ovum, and the endeavour to save the patient. In cases such as those I am now speaking of, where there is profuse flooding, the former is not likely to be successful; consequently, your attention must be more especially directed to the second indication, which can only be fulfilled by the expulsion of the ovum. Now, you are aware that, in order to effect this, the uterus must contract, and the os uteri must become dilated, and the ovum must become detached, before its expulsion be effected; but you must bear in mind that while these processes are taking place, the patient may die of hemorrhage, unless some means be taken to arrest it. The best mode of fulfilling this indication is by plugging the vagina. This will control the hemorrhage, and give the os uteri time to dilate without exposing the patient to any further loss. The kind of plug you should use is of some importance. Smellie recommended pieces of charpie or lint to be introduced, until a plug of sufficient size has been formed Burns advised the use of a napkin or soft towel, rolled up in the form of a plug, and introduced in that state. Some practitioners have advised that a lump of ice should be inserted in the centre of the plug. Dr. Dewees, of Philadelphia, has advised the use of a piece of sponge, dipped in pretty strong vinegar, and well squeezed out. By means of a string attached to the sponge, it may be withdrawn when necessary for examination. This is the best form of plug with which I am acquainted, and I strongly recommend it to your notice. The blood saturating the sponge becomes coagulated by the vinegar, and thus a firm clot is formed in the vagina, with the sponge as its nucleus, which effectually prevents the escape of any blood. It produces no undue distension or irritation of the vagina, and is neither difficult to introduce nor painful to retain.

In all cases of premature expulsion it is of importance to be aware if the ovum has come away. On examination we may sometimes feel a soft mass projecting slightly from between the lips of the os uteri. This may be a clot, or it may be the ovum. Should it be a clot, it is soft but not elastic, it is irregular in shape, and neither becomes tense during a pain, nor does it advance lower. Should it be the ovum, it has a convex, spherical or conical form, it is tense during a pain, it is loose and bagging between the pains, it also protrudes more and more through the os uteri with each pain. It may be removed by the finger used as a hook, or by two fingers used as a forceps, and when removed the uterus contracts, all hemorrhage ceases, and the patient recovers from her faintness. I attended a case of this kind a few days since. When the hemorrhage is not very severe the three grand remedies to be relied on are rest, the plug, and cold; but I must caution you against the too long-continued application of cold, as it thus becomes a powerful sedative, producing symptoms of collapse which may prove serious. Dr. Dewees speaks very highly of the power of acetate of lead over uterine hemorrhage. He says that, "In many cases it seems to exert a control over the bleeding vessels as prompt as the ergot of rye does over the uterine fibre." I have personally no information to give you respecting this remedy, as I have always found the means I have before mentioned sufficient, and consequently I have never employed it. Gallic acid may also, perhaps, be useful, administered as a styptic. If the hemorrhage be very profuse, you must endeavour to remove the ovum as rapidly as possible, and, as I have before told you, this must be done by exciting the contractions of the uterus. In some of these cases vomiting occurs, and this, to a certain extent, is useful, by rousing the uterus to contraction, and promoting the separation and expulsion of the ovum. You must watch the vomiting, however, to prevent its too long continuance, as it may be injurious; when it does not cease spontaneously you may have the abdomen rubbed with camphor liniment and laudanum.

In all cases of premature expulsion, examine the napkins carefully to see if the ovum has come away. When you know that nothing has passed, and you feel the ovum within the os uteri, you may pass up a syringe to inject a powerful stream of tepid water. This was first recommended by Levret, and you will find it generally successful. In private practice you should have a bed-pan placed under the patient before using the syringe, as by this means the bed will not be wetted. Dr. Dewees has recommended the use of a wire crotchet when the ovum can be just felt within the uterus; but I consider an instrument of this kind must be dangerous when introduced into the cavity of the uterus so as to be out of reach of the finger, and it only tends to break up the ovum. The ordinary dressing forceps, or nasal polypus forceps, are much safer for this purpose. You must always bear in mind in premature expulsion that the larger the ovum the more easily will it be expelled, and, consequently, it is wrong to attempt to break it up, or to bring it away in shreds. The uterus always contracts more firmly on a large body than a small one. When abortion occurs after the fifth month, however, this rule no longer obtains, as the ovum has attained a considerable size. You may, therefore, in these cases rupture the membranes should they remain long unbroken, and you will find that the escape of the liquor amnii will hasten the contractions of the uterus, and bring about the expulsion of the ovum more quickly. With regard to the after treatment of patients who have aborted, the symptoms are very various, and you must be guided by them almost entirely. It will be advisable for the patient to remain in bed for several days, of course; and afterwards, if she be much reduced, a mild course of tonics with country air, or a residence by the sea-side, and chalybeates, will be necessary. In cases when the patient has suffered severely from hemorrhage, beef-tea in small quantities and frequently repeated will be immediately necessary.

NATURAL LABOUR.

Having finished the consideration of those morbid conditions which are liable to occur during the various periods of pregnancy, I now pass on to the subject of *natural labour;* and I shall first say a few words respecting the *classification of labours*. As early as the time of Hippocrates attempts were made to classify the different kinds of labour, and strangely enough, the division then was much the same as in the present day—into natural and unnatural labours. The ancients, however, included in the class of natural labours those only in which the head presented, whereas experience tells us that labours may also be perfectly natural where other parts of the child present. Labours were divided by Rœderer, of Göttingen, into natural and artificial, and the latter were subdivided into manual and instrumental, these being again classified into forceps' cases, &c. Dr. Smellie divided the process of labour into natural, laborious, and preternatural. Dr. Denman classified labours as natural, difficult, and anomalous. The great divisions at present in use are obtained from the continent, and are divided into eutocia, signifying natural or favourable labour, and dystocia, faulty or unfavourable labour. This is the arrangement which I consider the simplest, and which I shall accordingly use.

Natural labour requires to be thoroughly well understood, not only with respect to the changes that occur in the mother, but also as regards the changes in position of the child as it passes through the mother's parts. Labour is generally considered as being divisible into stages, and in this country it has been usually divided by authors into three stages. The first of these stages commences with the beginning of labour pains, and ends with the dilatation of the os uteri; the second stage begins when the os uteri is completely dilated, and ends with the expulsion of the child; and the third stage commences after the expulsion of the child, and ends with the expulsion of the placenta. In the German schools labour is, however, considered to be divisible into five stages, and as I think the subject may be better explained under this system of classification, I shall adopt it. Under this division the first stage commences with the first perceptible contractions of the uterus; these produce no pain in the healthy state, and often come on two or three days before the actual beginning of labour. These pains make themselves evident to the patient only by the feeling of equable tension and pressure round the abdomen to which they give rise, and have no effect on the os uteri. They are called the *dolores præsagientes*, and are described as follows by Leroux:—"The first contractions are feeble, and communicate no sensation to the patient; in order to discover them, we must place our hand upon the abdomen; if we feel the globe of the uterus raise itself and become hard, this is a true contraction. These contractions gradually increase until they excite pain, but pain is not essential to contrac-

tion—it depends on the distension and compression of the nerves produced by the resistance of the body upon which the uterus acts, and increases in severity in proportion to the degree of resistance and contraction." These pains usually come on towards the evening, and as the night advances again go off. They are seldom felt to any extent, unless there be intestinal irritation present, or the patient be of a rheumatic diathesis. The patient is generally restless, and cannot remain long in the same position; she appears to suffer from a general feeling of malaise. There are frequent calls to relieve the bladder and rectum. The os uteri is now felt backwards, and high up in the hollow of the sacrum, so that you find it difficult to reach it with your finger. In a primipara there is no longer any trace of cervix uteri; the os uteri feels like a circular dimple, which is closed and sealed up by a plug of gelatinous matter. In a multipara, on the contrary, the cervix can be felt, especially if she have borne many children, the os uteri being neither so high nor so far back as in a primipara. The cervix also presents to the finger inequalities and irregularies, the result of cicatrices, in consequence of former labours; it is also more or less open during the last days of pregnancy. In the primipara the head is deep in the cavity of the pelvis, in consequence of the entire disappearance of the cervix uteri In primiparous females, when the os uteri begins to dilate, its edge is exceedingly thin, like parchment but, as the first stage of labour concludes, and the *second stage* commences, it becomes thicker and softer. It is slightly tense during the pains. The vagina now begins to swell, and this swelling is soon followed by a considerable secretion of thick albuminous mucus. The more albuminous this discharge is, the more copious is its secretion, and the more easily does the os uteri dilate. I must here caution you against supposing that the os uteri is dilated by the mechanical action of the child's head pressing it open in the manner of a wedge; its enlargement is owing to the complete relaxation which takes place of the circular fibres, the longitudinal fibres acting with increased vigour, and pulling, as it were, the os uteri asunder. This relaxation of the circular fibres is shown by the swelled and cushiony feel of the os uteri, and the more this organ puts on the condition described, the more easily does its dilatation go on. I insist most strongly on this point, as in many of the periodicals even of the present time I perceive cases reported in which the os uteri is said to be *thin and dilatable*. Now, Gentlemen, I assure you that the concurrence of these circumstances is impossible. Indeed, if by too frequent examinations, or any other mismanagement, the secretion of mucus be arrested, the vagina becomes hot and dry, and as if raw to the feelings of the patient, the dilatation of the os uteri is immediately stopped, and if this process of inflammatory action be allowed to go on, you will place your patient in considerable danger. The pains become less regular, less protrusive, and, at the same time, more distressing to the patient, for she has now no intervals of relief between them. There is no chance of a comfortable doze, the tongue becomes dry, and general fever and constitutional irritation are set up. In these cases you must either bleed or give salines with the warm bath. Bleeding is generally followed by the best results, and often in a few minutes the patient, who was in a perfect state of fever, is again well. The secretion of the parts returns in abundance, the pains become effective, and the labour progresses very rapidly. So far, Gentlemen, we have been considering the dolores præsagientes constituting the first stage of labour. The *second stage* comprises the dilatation of the os uteri, and now the patient is no longer able to conceal her pains. If walking, she is obliged to stop and support herself until the pain is over. When the os uteri begins to dilate the pains are felt in the back and loins; they come on and go off gradually, and leave the patient quite free during the intervals. During the progress of a pain, the pulse shows a slight increase in rapidity, which again diminishes as the pain subsides. M. Hohl has advised the pulse to be counted every quarter of a minute during a pain, and gives the following as an illustration of its rise and fall during a pain of two minutes:—18 during the first quarter, 20 during the second, 22 during the third, 23 during the fourth, 22 during the fifth, 20 during the sixth, 18 during the two last. The os uteri now undergoes considerable changes. Wigand says, "In women who have already borne children, the os uteri is at this moment much lower than in primiparæ; it is thick, soft, and cushiony, communicating to the finger a spongy feel; it is cool, having quite relaxed during the intervals of the pains, and so yielding that two or more fingers can pass; the thin, hard, distended os uteri at the beginning of the labour exerts a much greater resistance against the head than when it becomes thick and swollen, for, in the latter case, the fibres being separated from each other by the swelling, it becomes more dilated." As regards the intervals of the pains, the fundus uteri, on external examination, is found to be soft and relaxed. The prominent parts of the child may be felt through the abdominal parietes together with its motions. The patient, in healthy labour, is quite free from pain during these intervals, and sometimes gets a short and refreshing doze. The os uteri will be found slightly dilated, and it may be pulled about in any direction. The membranes have receded, and the presenting part of the child can be easily felt through them. When the pain again commences the membranes become tense and protrude, the whole uterus becomes hard, and the prominent portions of the child indistinct. It has been stated that these pains commence in the fundus uteri and gradually extend downwards to the thighs, but exactly the reverse of this obtains, for the contraction commences about the os uteri and gradually spreads over the body and fundus. Pains continue to recur in this way till the os uteri has assumed a dilatation of about two inches and a half, which ends the second stage of labour.

At our next meeting, Gentlemen, I shall resume this subject.

Clinical Lecture,

BY DR. CORRIGAN,

Delivered at the Whitworth, Hardwicke and Richmond Hospitals, Dublin.

Abdominal Tumour—Fremissement in Abdomen—Mode of its production. Clinical Observations.

Mary Lester, aged twenty-six, admitted into Whitworth Hospital on the 23rd of February, 1846, with swelling of abdomen, which first appeared five weeks previous to her admission. A tumour, semi-elastic, of considerable size, but indistinct in its outline, is perceptible in the umbilical region. The tumour can be pushed a little from side to side, and on pressing the abdominal parietes over it, a distinct fremissement is perceptible. On percussing over the tumour there is hardly any increase of dulness; the action of the heart is very quick; she is suffering under occasional vomiting of greenish fluid. The tongue is red and dry; the bowels costive, and the urine high coloured; catamenia irregular.

For the last six months she has suffered from dysmenorrhea. About thirteen weeks since she had palpitation of the heart, succeeded by pain of the left side of the abdomen and frequent micturition. On her admission she was leeched on the epigastrium, and she was put on mercury, with occasional purgatives. She grew thinner and weaker day by day. About the 12th of March, irritative fever was strongly developed, marked by a feeling of burning over the whole body coming on every evening, and the sensation of burning through the abdomen became more troublesome. She was again leeched, and an anodyne draught was given every night.

On the 16th the stomach became very irritable; she had frequent vomitings of greenish fluid. For this she was ordered a blister to the epigastrium, and the following:—

R. Boracis, ℈iv.; Aquæ ℥ viij.; M. ℥j. ter in die.

19th. The vomiting continued; the pulse became very small, and the emaciation was very marked.

On the 23rd the following note was taken:—There is no vomiting, but the tongue is dry at tip, and coated yellow. The emaciation is rapid; the skin dry and scaly. She lies heavy in bed on her back; her countenance sunken; she complains very much of severe cutting pains through the abdomen, accompanied with very frequent discharges of orange-coloured mucus. The tumour in the abdomen is more perceptible between the umbilicus and right iliac region, and is somewhat tender under pressure. On pressing over it loud borborygmi are caused, and on percussing it there is hardly any dulness perceptible. There is cough, accompanied with light mucous rattle and distinct bruit de soufflet under left mamma. The pulse is very weak and intermittent, and over the skin of the chest a great number of stigmata of purpura are scattered. Wine and opium, in injection, were administered, and a blister applied over the epigastrium. She died that night.

Post-mortem.—The lungs are quite sound; there was, as I have said, a bruit under the left mamma. I have not yet, however, examined the mitral valve, but, observing the shape of the heart, its apex being formed by the left ventricle, I should say beforehand that we shall find the mitral valve sound. I may observe that, in cases such as this, of great debility and progressive anemia, a bruit is not evidence of valvular disease unless accompanied with evidence of mechanical obstruction. The aorta and its valves, I find, are quite sound, as is also the auriculo-ventricular valve; thus, you see, no value is to be attached to the presence of a bruit in the absence of the other signs of obstruction; its existence here, together with the increased action of the heart, was owing to the disease of the abdomen, to which we shall now turn our attention. On turning back the abdominal flaps, their peritoneal lining membrane is seen to be covered with lymph of considerable thickness, divisible into layers, and mixed with a kind of fatty deposition, very curious in its appearance. All the intestines are covered with the same cheesy, granular deposition, the stomach, liver, gall-bladder, &c.; the mesentery, meso-colon, descending-colon, and rectum.

Now, if we proceed to examine the tumour, and place it in situ, covered in this way with a double fold of cloth, you find, if you take the trouble to examine it, that it conveys through the cloth pretty accurately the sensation that it did during life through the parietes, and you will find it exceedingly useful in examining morbid specimens, to place them as this now is as much as possible in the position in which they lay during life. The tumour was situated between the umbilicus and the left iliac region, and had, as it now conveys through the cloth, a very deceptive feel, half solid, half elastic. A number of these signs, I may observe to you, are as well studied on the dead as on the living subject, because they are physical, and some of our best works have been the result of observations in this way, foremost among which, perhaps, is that by Piorry. Before unravelling the tumour, or seeing the mode of its formation, I may remark a curious fact connected with it during life; I allude to its not having yielded a dull sound on percussion. You now perceive that it is formed in a singular way of convolutions of the intestines coiled and knotted together by means of the cheesy, granular material, such as is deposited elsewhere and which binds them all into one mass. The tumour, you can perceive, is more or less analogous in its physical characters to a bladder distended with air, inasmuch as it glides about under the hand, and you cannot move one portion of the mass without the whole. During life borborygmi were heard over the tumour, so loud in the intestines, when pressed with the hand, as

to be audible at some distance; but to this we did not at the time attach much value; but it is a circumstance well worth remembering, as its occurrence in a tumour, or immediately over it, the intestines being pushed aside, may in future instances assist us in the diagnosis of the nature of the tumour. You may perceive that the cœcum is involved in the tumour, the whole of the jejunum and the greater part of the ilium—in fact, three-fourths of the whole mass of the small intestines. Then there is mesentery containing also this lymphy deposition, and forming the solid portion of the tumour; this solid material, too, can be observed to exist to the depth of an inch when the air is expelled from the intestines. Next, with respect to the fremissement observable over the tumour, I have some observations to make. Some of the French writers—I believe Piorry—say it is indicative of the presence of hydatids.

Dr. Bright, who has published his views on the subject, attributes it to the existence of adhesion between the intestines and the parietes, or between the liver and the parietes, and has referred to diseases of the liver in which this condition has been found; but there is a want in the link of evidence which he cites, to prove his theory: for instance, he relates it thus:—You may suppose, for the purpose of description, that, on the 1st of February, he detected fremissement, and that, on the 24th, the patient died, after a lapse, we'll say, of three or four weeks; and finding that adhesion had taken place, he set down the fremissement observed in the beginning as a sign of the occurrence: we do not hear, you observe, whether the adhesion did not take place subsequent to the date at which the fremissement was noticed. This is a matter of importance, not merely in a theoretical point of view, but for practical purposes also, in the treatment of abscesses, ovarian tumours, foreign growths, &c., in which it is of exceedingly great consequence to be able to make an accurate diagnosis.

Next to Dr. Bright's cases, came one from myself. In that case, fremissement was observed every day up to the time of the patient's death, and when actually dying, yet no adhesion at all existed, but a large tumour of a foreign growth was found, which, by its friction against the parietal layer of the peritoneum coated with lymph, produced the fremissement. Thus, then, neither the presence of hydatids or adhesions are necessary to its existence, but the one fact of the formation of surfaces of lymph which, by their friction, give rise to the phenomenon. Dr. Beatty published a case in which, from the presence of a solid abdominal tumour, fremissement existed; and it was then inferred, that only under those circumstances could this sign be detected. But in the case now before us we have a tumour formed of coils of the intestinal tube, remaining perfectly free from solidity all through, not at all hard, yet fremissement was constantly observed from beginning to end. The only point to be determined now, therefore, is, whether a mere covering of lymph over the intestines, filled with air or fluid, as the case might be, and perfently free to move about, would be sufficient to give rise to the production of fremissement; but that is a point which must, for the present, be left undetermined. The patient, I may remark, was in the hospital for at least nine weeks, and her illness commenced about a month before, and originated in an attack of dysmenorrhea. She complained on admission of pain under the ribs of the left side; this had been present since the commencement of her illness, and lasted till her death, occupying a period altogether of thirteen weeks.

I allude particularly to the duration of this case for the purpose of directing your attention to the fact, that depositions of lymph in internal organs will remain in a state capable of undergoing absorption, sometimes for so long a period as three, four, or five months. You see the extent to which lymph has been shed here, involving the whole abdominal wall, and covering the stomach, liver, &c., rendering it out of the question that absorption could have been effected, when the inflammatory process had been of such duration, but you observe the lymph in a soft, organisable state, perfectly capable of absorption under other circumstances. This is a fact of considerable consequence, as showing how necessary it is to push mercury in inflammatory affections of the internal organs. Its advantages are especially observable as regards the absorption of lymph from the pericardium and valves of the heart. On looking to the large intestine, you observe that the folds of mucous membrane in the rectum are more vascular than natural, owing perhaps to the action of the mercury. In the rectum are some remains of the orange-coloured mucus which was discharged during the last hours of the patient's life, and on the mucous membrane of the same substance are numerous small spots of greyish lymph, such as are met with when the rectum has been the seat of considerable irritation. The uterus appears to be healthy. In conclusion, I may remark, that the case is one you have not often an opportunity of seeing, and involves some important points of diagnosis, referable to the value of fremissement when present so extensively as in this case, through means of which, with the other symptoms trifling in amount, we were enabled immediately on seeing the patient to form our prognosis. Again, the case is of importance as affording us information upon the pathological fact, that lymph after so long a time remained in great part in a state capable of absorption.

A Course of Lectures on Diseases of the Skin.

By JAMES STARTIN, Esq., Surgeon to the London Cutaneous Institution.

LECTURE XI.

LICHEN AND STROPHULUS (continued).

GENTLEMEN,—I have the pleasure to-day of introducing three well marked cases of lichen for your examination. The patients have in every instance applied within the last ten days, so that you have an opportunity of observing the disease before much has been done to alter its appearance. On a future occasion you shall witness the effects of the curative measures employed. The first case is one of lichen simplex, which you will find very closely corresponds with the model before you. The second case is a fine example of lichen agrius, of ten months' standing; and the third is the instance of L. lividus of which I last week made mention.

The first species of lichen, then, to which I would call your attention is L. papulatus or simplex, and the variety is that I have designated sparsus. The patient from whom the model was taken was David Bailey, aged thirty-six, of Dorset-court, Salisbury-square. He was admitted on the 17th of October last, after being affected three days only. The eruption was preceded by languor, lassitude, and feverishness. In the course of the night a sensation of creeping and tingling manifested itself in the arms and upper parts of the body, which was soon followed by an eruption of red papular spots, which are represented rather too large and red on the cast.

This man could give no cause for his complaint beyond the slight indisposition already mentioned, which for a few days preceded the eruption; but his pulse was full, his tongue furred, and much heat of surface existed. He suffered severely also from irritation, and could scarcely hold a short conversation without rubbing or scratching himself. At night he described this itching as much augmented, so that he was obliged to lie out of bed. When he applied to the Institution the eruption had extended over the whole body, much in the manner represented in the arm by the modeller. In a few situations the disease had become confluent, several papulæ having, as it were, coalesced, so as to form a small irregular patch the disease.

To relieve these symptoms this patient was directed to be bled to eight ounces, and purged with sulphate and carbonate of magnesia, containing small doses of the wine of colchicum, and the tepid bath was ordered once or twice a-week. At the end of seven days he had experienced great relief from the measures employed; but the eruption had not materially declined, though less irritation existed. An alterative mercurial twice a-day was now prescribed, and the vapour, instead of the tepid bath, whilst a lotion of creosote-water and bichloride of mercury, one grain to one ounce, was to be used warm to the parts when itching came on. He continued these alteratives for a fortnight or thereabouts, when, as nothing but an almost imperceptible furfuraceousness of the parts affected could be discovered, and he was otherwise in perfect health, on November 4th he was discharged cured—his malady having lasted about three weeks, which is its usual course.

The model to which I now point would be called in Willan's nomenclature strophulus confertus. I consider it lichen simplex confertus in the young subject, and I would precisely define it as L. simplex infantilis confertus; as it extended all over the body, it would belong to the division generalis (general infantile clustered lichen). This cast was taken from Edward Higgins, of Clarence-gardens, Regent's-park, who had suffered upwards of a year from the disease, which no doubt originated from the irritation of dentition; but as this process had been completed some months in this child, who had the usual number of sixteen teeth, it appears to be continued from some other cause, perhaps derangement of the alimentary canal, induced by the continued irritation and imperfect performance of the functions of the skin; this view of the case was verified by inquiry into the child's evacuations, which were unhealthy and offensive, yet there was little loss of flesh, and the child had a somewhat robust, though strumous appearance. He was directed to take three times a-day about one-tenth of a grain of biniodide of mercury (formed extemporaneously as I have before mentioned, by adding a solution of iodide of potassium to one of bichloride of mercury), and this was combined with tincture of opium in minim doses. The whole body was also directed to be washed daily with the yoke of a fresh egg in a bath of tepid water, and after drying with soft linen, an ointment, composed of bisulphuret of mercury and creosote in small proportions, was to be smeared over the parts affected, his diet was ordered to be chiefly milk and boiled meats, and all internal and external sources of excitement were to be avoided. By the steady perseverance in this plan for a month, till November 21st, the quantity of the biniodide of mercury being rather diminished than increased, this little patient became entirely free from his troublesome disease, which from the great irritation attending it, "had never," as his mother assured me, "let her have a night's rest since the rash broke out."

Another case of lichen simplex confertus, occurring in adult life, I shall shortly relate, as I have previously referred to it, in consequence of the exciting cause being rather moral than physical. Ellen Wade, aged thirty, of Broadway, Blackfriars, was admitted on the 7th of November last, presenting a well-defined case of lichen confertus, which had tormented her for four months, during which time she had been treated elsewhere for a better known cutaneous disease, which, however, only increased her sufferings. She was a servant where a boy was kept, and said that this youth had "worretted her very much," and on one occasion had caused her so much alarm that she went to bed ill, and could not sleep all night from the tingling, smarting, and itching all over her body, which in the morning she found arose from the eruption of a red pimply rash. This woman was of weak intellect, and subject to hysteria. The whole of her body presented a similar appearance to that offered by the model to which I last directed your attention, though less inflammation existed, and the parts were not so much irritated by scratching; I could find no organic derangement in this patient's general health, and therefore at once

proceeded to endeavour to excite another action in her skin by the internal administration of bichloride of mercury in one-sixth of a grain doses, and a lotion to be used warm of a weak solution of the same salt in creosote water; the use of soap was interdicted, her diet regulated so as to be mild and nutritive, and an occasional tepid bath was ordered to be used for half an hour at a time. These remedies and measures she continued for a fortnight only, with daily amendment so that on the 21st of November she was discharged cured, with directions to continue her diet and tepid baths for a short time.

I have no model of lichen pilaris, which differs only from the other varieties in ha ing its seat in and around the hair follicles, it is a comparatively rare disease, and is not very well shown in Willan's plate, which I hand round, and could only be imperfectly represented by a cast, as it extends deep into the dermis, and the hairs become implicated in the disease, and fall off after a time; it is usually very troublesome to cure, though I have seldom failed, after a month or six weeks' perseverance As a case of this variety of lichen presented last Monday, I shall briefly relate it, and this I do inasmuch as I have some hairs to show you through the microscope, which you will find worthy of your attention:--

Benjamin Jones, aged forty, was admitted on Monday last, having suffered, as he states, six months from an eruption confined to the upper and back part of the head, and the lower and front part of the abdomen, extending from the umbilicus to the pubes; this first appeared like small red pimples, which itched a good deal, and were soon attended by a partial fall of the hairs of the parts affected, whilst their roots still continued slightly inflamed and itchy; he could assign no particular cause for the complaint, unless it were poor living. The appearance of the lichen on this man's abdomen was very much like that represented in Willan's plate; but the papulæ were larger, and of a deeper red, whilst on the head they had almost assumed the appearance of a variety of porrigo decalvans, not the smooth baldness, but a more uneven variety, where each root of the destroyed hair seems thickened and enlarged, so as to raise the skin around it in a slightly conical form. As he had an asthenic appearance and a languid circulation, the persulphate of iron in infusion of quassia was directed, whilst he was told to apply an ointment composed of white precipitate of mercury and levigated sulphur in fresh lard to the parts affected Of course, we cannot yet learn the result of this case, which may last two months before relief is obtained.

The variety of the complaint under our consideration, that I have called L. agrius inveteratus, is the L. agrius of Willan, and it may be chronic or acute. I directed a cast to be made of this disease, though the modeller has failed in producing so good a representation as usual.

Mary Salisbury, aged forty-five, a servant, from the severity of the disease, which had afflicted her upwards of two years was obliged to leave her place. Her first application to this institution was on the 4th of April, 1845, and she was discharged cured, and returned to her place May 21st; but as her occupation was in the kitchen, the heat and dust occasioned a return of her complaint in the beginning of July, and it increased much in violence and severity, her arms, neck, and face being chiefly affected till the 21st, the date of her second application, when her condition was as follows:--The face, neck, and arms were of a deep red colour, from the numerous papulæ which everywhere covered their surface, though a mottled appearance was created by the pimples having become confluent in some places, where the irritation had been apparently so great as to oblige the patient to remove the points of the papulæ by scratching; a few slight crusts occupied some of these patches, whilst in others, particularly near the flexures of the joints, and in the folds of the integument of the neck, superficial excoriations existed, which, however, were not smooth, as in erythema intertrigo, but rough and papular. Every stage of lichen could be witnessed in this patient—thus, the first blush of redness, the papulæ on their early development, when they begin to die away or decline, and the scurffy state of the surface left by their disappearance, whilst the inveterate nature of the eruption was manifested by the slight crusts and excoriations before described, and the violence and continuance of the disease. This woman could give no cause for the origin of the disease, but regarded it as a critical eruption depending upon her age (forty-five), and the departure of the catamenia, though this periodic evacuation had not finally disappeared.

No information could be gained of this patient's previous habits, except her own statement that she was not addicted to any kind of excess. The irritation attending her malady was so great as to prevent her resting day or night; indeed, she went nearly without clothes, that she might indulge the painful luxury of scratching, though blood followed each attempt of the kind, with an increase, rather than any diminution, of her sufferings. This continued irritation and want of rest had somewhat deranged Mary Salisbury's health, which was evidenced by a feverish state of system, a hot skin, and frequent pulse. The immediate indications, therefore, were to regulate these morbid phenomena by appropriate remedies, which consisted of purgatives and diaphoretic diluents, with a strict regulation of the diet, whilst the surface was cleansed with mucilaginous baths and ablutions with yolk of egg and water, or thin warm gruel. At the end of ten days or so, these preliminary measures had much moderated the violence of the lichenous disorder, and still more improved the condition of the general health; consequently, a solution of a quarter of a grain of iodine, in twenty minims of liquor of potash, and ten drops of the wine of colchicum, were directed to be taken three times a-day, whilst an ointment of creosote was smeared over the more irritable parts of the eruption; the baths, &c., as before. These means were continued with little interruption and some benefit for a month, till September 1st, when a small proportion of mercurial ointment was added to her external application, and a dose of calomel and opium was taken at bedtime. By the 22nd of September the amendment was very palpable, but the lichen seemed, for a short time, to have been stationary, so that the counter irritant system was thought advisable, and, in consequence, one-sixth of a grain of biniodide of mercury was substituted for the former internal remedies, and a lotion of bisulphuret and bichlorid of mercury in small quantities, suspended in water; to be applied warm to the diseased parts.

On October 20th, three months from admission, the patient was by these means freed from her tormenting disease; but the skin was harsh and dry, and the general health but indifferent; so that the mercurials, internally and externally, were discontiued, and a lotion containing a little borate of soda and glycerine was ordered as an outward application, whilst an aperient chalybeate, with an excess of sulphuric acid, was taken as a tonic. She was also recommended to use a tepid bath once a-week, which might contain a little bay-salt, i. e., salt obtained by the evaporation of sea-water. She was dissuaded from resuming her avocation of cook. I last saw the patient on the 17th of November, four months from her first attendance, when she was quite well.

I have directed the patient suffering from lichen agrius to attend again a fortnight hence, to show you the disease after a three weeks' course of mercurials, internally and externally applied, with the use of the vapour-bath, when, should his disease present any features worthy your notice, I shall have much pleasure in pointing them out. With respect to the other varieties of lichen mentioned on the chart before you, and which I have already described, the species you saw in a patient before the lecture, which Willan called lichen lividus, is so rare a disease that I must refer back to the past year for a single case; this was an individual employed in the type-foundry of Messrs. Caslon and Son; he was a stout, plethoric man, and looked like a stout drinker. On his application his whole body was covered with lichen, which would have been called sparsus had it not been intermingled with petechiæ and livid blotches, as though he had been bruised; it came on suddenly, without any assignable cause, and quickly yielded to an acid chalybeate, with the use of the hot air bath and sulphur fumigations.

L. infantilis, or strophulus, scarcely deserves special illustration by a case. If the teeth and gums meet with due attention, and any bodily derangement be regulated with alkalines and mild mercurials, all that is needful will be done, save that soap and all irritants must be kept from the papulous parts.

Lichen urticatus is a much more obstinate variety of the disease, and in my hands has often proved more intractable than those hitherto detailed. This arises, I believe, from its being commonly symptomatic of some derangement in the circulation, and disease of the heart or blood-vessels, evinced by fainting fits, dyspnœa, palpitation, and irregularity of the pulse; and remarkably shown by the patient who presented himself on Friday last, and whose case I will relate.

Wm. Fisher, aged fifty, of Princes-street, Borough, attributed his malady to constant exposure to the night air in attending on a sick wife four years ago, since which he has been more or less tormented by this disease, which has resisted every means attempted for its cure, though he has never been away from medical treatment since it commenced. The pulse of this patient was not more than 55 or 56, and intermitted occasionally; I did not listen to his heart, or I have no doubt I should have found mischief there. He had a sallow, cadaverous look, and seemed almost bloodless. The disease of his skin—a well-marked instance of lichen urticatus—showed very little, but his agony was intense, as evidenced by his anxious countenance; indeed, he described the itching as mixed with pain and burning that defied description; in this respect the complaint resembled the next variety of disease to which I shall direct your attention (prurigo). Of course, I have little hope of benefitting this patient, at least as an out patient. I have ordered him small doses of carbonate of iron, and the use of mucilaginous baths, but he ought to be the inmate of a sick ward, to enable him to receive all the benefit our art is capable of affording.

Lichen tropicus is the last species of the disease we have been considering; but as this belongs to other countries, being only accidental in this climate, I shall add nothing to the definition of the disease I have already given. Yet, in an institution like the one in which we are assembled, where nearly 3000 patients suffering from diseases of the skin are annually entered on the books, every form of cutaneous disorder must soon become familiar, whilst the effects of the treatment employed are equally apparent; and, therefore, maladies like lichen tropicus, which may occur but once in the practice of an individual, will here display little semblance of rarity, an instance of which has this day been offered to your observation in the case of the poor man you have seen suffering from lichen lividus, which is so rare an affection, that Rayer, the author of the admirable treatise "*Sur les Maladies de la Peau*," with the nearly boundless opportunities of observation which the practice of the Hospitals St. Louis and la Charité afforded him, affirms that he has twice only witnessed this species of lichen. It is the wish of the committee of this institution that the practice, medical and surgical, should be thrown open to pupils, under similar regulations to those of the Ophthalmic Hospital, so as to give all who desire it an opportunity of studying in the book of nature the diagnosis, prognosis, and treatment of chronic diseases of the skin; and I do not hesitate to affirm that you may see more of these

complaints in this establishment in six months than in the largest hospital in the United Kingdom in six years, or perhaps in an entire life. Two hundred cases on an average attend three times a-week—Mondays, Wednesdays, and Fridays—and sixty new examples constitute the weekly average entered on the books. Each patient on his application, which is not necessarily accompanied by a governor's recommendation, has the origin and nature of his disease inquired into, when the name of his malady and its previous duration are entered in the register; his age and any other circumstance deemed of importance being also notified; then the medicines, applications, baths, diet, &c., are specified, and the indications from which they have been directed are explained to those gentlemen who attend. At each subsequent visit the results of the treatment and required alterations are in like manner inscribed in the register; so that at the termination of the case a mere glance is all that is necessary to see what has been done, and with what effect. It must be obvious that by such means, comparisons and deductions may be at once arrived at, which could only be obtained by the great labour of reporting and collecting the detached cases occurring at a general hospital through a long series of years Indeed, it is only necessary to witness the immense succession of important cases for half an hour on any of the days appointed for the attendance of the patients of this Institution, to become convinced, not only of its utility, but necessity, as the sufferers, in the majority of instances (at least, in fifteen out of twenty cases), present no light or trivial disorders which are to be relieved by a simple panacea; but their maladies will be found to have existed for a series of years, and to have resisted the efforts of public and private medical treatment; so that a long attendance and carefully regulated therapeutics become the *sine qua non*, if a cure or relief is to be obtained. Let it be recollected also that these complaints are under the eye of the patient, who has thus a double test to inform him whether his condition improves or retrogades

It often perplexes me to account for the very few cases of scabies that present themselves, and my attention has latterly been particularly drawn to this fact as the time I have fixed for decribing this common malady approaches, and I have sought in vain for the past two months for suitable cases on which I might employ the modeller to illustrates this subject; he has even offered to contract the disease himself by way of relieving me from my difficulty, which at any rate you will allow to be pressing enough, when I have this day to announce that the next chronic diseases of the skin to which I shall request your attention are three affections which have itching for their most prominent symptoms, viz., prurigo, porrigo, and scabies. The first of these maladies, however, will furnish us with abundant matter for next week's consideration, when I trust again to have the pleasure of meeting you.

REPORTS ON DISEASES OF FEMALES.

By EDWARD RIGBY, M.D.

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery in St Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

FIBROUS TUMOUR.

(Continued from page 81.)

The early history of the case I last reported is such as to have induced a conviction in the mind not only of the patient and an experienced female friend, but also of her medical attendant, who had watched her with the greatest care, that she was pregnant. Having had a slight catamenial discharge in the two first months of her former pregnancy, the irregular and scanty appearance of it in the present case did not invalidate this supposition. The attack of flooding in consequence of her fall, and the expulsion in the course of some weeks after, of what appeared to be the contents of a pregnant uterus, tended to strengthen this opinion. Unfortunately, I neglected to ascertain whether it was considered at the time to be a miscarriage by the practitioner himself. The undiminished size of abdomen, and commencement of the sensation of internal movements like those of a child, which were examined and pronounced to be so by an experienced female friend as also by the medical attendant, seemed to remove all doubts upon the subject. She was now about six months advanced in her supposed pregnancy. From this time her symptoms became more questionable, and less indicative of the gravid state. The abdomen, so far from increasing in size, was gradually but perceptibly diminishing, so that, by the time I saw her she was not much above her ordinary size. She became liable to attacks of severe pain, and bilious derangement; had returns of what she then supposed to be hemorrhage, but which in all probability were nothing more than rather profuse catamenia, and had now the constant sensation of a foreign body in the lower portion of the abdomen.

Although a hard, deep-seated, and intensely painful mass could be plainly felt extending across the abdomen, and apparently in contact with, or arising from the posterior wall of the uterus, yet the smallness of the cervix and lower part of the uterus, as reached per vaginam, the circumstance of the sound passing only two inches and a half when I introduced it, thereby indicating that the cavity of the uterus was of the natural extent, and above all, the history of the case itself, all led me to form a very different opinion to that which I afterwards arrived at with the aid of Professor Simpson's tact and experience.

Although there could be no doubt that the opinion respecting her being pregnant, as founded on the supposed movements of the child, was evidently erroneous, yet the early history of her case strongly inclined me to suppose that pregnancy had *once* existed, and that it had come to an abnormal and unusual termination. Supposing that she had therefore been pregnant in the early part of the year, the case appeared to resolve itself into one of two conditions, either that of extra-uterine pregnancy of the ventral character, or that it had become so in consequence of injury to the uterus at an early period of natural pregnancy. The history of the case disposed me to adopt the latter view: an accident had occurred, viz., a severe fall, from which I considered that rupture of the uterus might have been the result, that the fœtus had passed into the abdominal cavity, and had formed a sac for itself, which was the painful tumour I had felt through the abdominal parietes; even the circumstance of the uterine sound passing to a greater distance than was natural, so as to be distinctly felt with the hand externally at a considerable distance above the symphisis pubis, did not seem at first to invalidate this opinion, because well authenticated cases are on record of the uterus having evacuated its contents into the abdominal cavity in consequence of rupture, the result of injury at an early period of pregnancy, and where the patient has ultimately discharged the fœtus in portions by abscess as in extra-uterine pregnancy. The extreme rarity of such cases on the one hand, and the frequent occurrence of fibrous tumour on the other, render the probabilities of chance strongly in favour of the latter condition. Fortunately the treatment required for either was not very different; the extreme tenderness of the mass indicated considerable inflammatory action, and leeches were repeatedly applied vith the best effects. The gradual and uniform diminution in the size of the mass, with an improvement in her symptoms, speaks rather in favour of its being fibrous tumour; for, had it been an extra-uterine fœtation, its size would neither have diminished so considerably, nor would she probably have been so free from pain, or have improved so remarkably in health as has been the case. The form of the mass is certainly not that which is commonly observed in fibrous tumour of the uterus; instead of being globular, with hard nodules here and there, and easily felt beneath the abdominal parietes when it has attained a certain size, it has a flattened shape, and lies at a considerable depth beneath the integuments.

The application of mercurial and other ointments is a valuable adjunct to the use of leeches in cases of fibrous tumour. In some I have mixed about a third or fourth part of iodine ointment with it, and when applied steadily for some time it has seemed to soften and diminish the size of the mass. I have occasionally introduced a male catheter, filled with ointment in a fluid state, and then discharged it into the cavity of the uterus by means of a flexible piston; but, at present, I have not had sufficient opportunities to enable me to speak with certainty of its effects beyond that it has not produced any irritation or unpleasant symptoms.

M. W., aged thirty, married ten years, once pregnant, but aborted.

March 9, 1839. Pain in the back, extending downwards to the rectum and round the hips to the symphisis pubis, with difficulty evacuating the rectum and bladder; bowels confined, fæces flattened. She began to suffer pain in the back, extending down the legs, and shooting towards the rectum a year ago; during the last four months she has suffered from piles and from occasional difficulty in passing water, which, last Christmas, became so severe as to require the catheter to be passed. This difficulty, however, abated, and did not return until last week, when she was again compelled to have the water drawn off. Her general health has been tolerably good, but her bowels are habitually constipated, the fæces being passed in a flattened form. Within the last two years she has had occasional leucorrhœa

Examination per Vaginam.—A large, hard, solid tumour was found distending the uterus, and nearly filling up the cavity of the pelvis. The os uteri pushed over to the left foramen ovale, and much squeezed and flattened by the mass. With some difficulty I succeeded in pushing this tumour above the brim of the pelvis into the abdominal cavity, through the parietes of which it could then be distinctly felt. The pain of back and pelvis, and the difficulty in evacuating the bladder and rectum, were immediately removed, and the patient felt greatly relieved.

May 25 Is in good health; the tumour continues above the brim of the pelvis, and causes but little uneasiness.

I have given this case merely to illustrate what I stated in my introductory remarks on fibrous tumour of the uterus, viz., that where it occupies the pelvic cavity, and fills it pretty completely, the symptoms which it produces by its mechanical pressure, and which sometimes amount to severe suffering and serious derangement of health, may be at once cut short by raising it above the brim of the pelvis. I cannot say that I have observed its increase of size to be accelerated by passing from a non distensible into a distensible cavity, and even if this were distinctly the case, the alleviation of her sufferings would render such a measure perfectly justifiable.

At the present moment I have a patient where a well-marked fibrous tumour of globular form can be slowly moved either out of the pelvic cavity into that of the abdomen, or, vice versâ, from the abdomen into the pelvis. In this case the mass, when I first saw her, was immovably fixed in the cavity of the pelvis; but by frequent application of leeches, and mercurial ointment with a little iodine, it has so far diminished in size as to permit of being moved as above mentioned without any degree of force.

Typhoid fever is causing dreadful ravages in the village of Maquinneville (Somme) and such is the terror resulting from contagion, that a man was recently obliged to bury his wife with his own hands.

FEVER HOSPITALS IN IRELAND.—The boards of guardians of the Castlebar and Callan Unions, have just given notice of their intention to erect fever hospitals in their respective localities.

MEDICAL CASES.

CASE III.

DELIRIUM TREMENS.

Ann Jones, aged forty, dressmaker, admitted May 20, by Dr. Nairne. Countenance pale; pulse 108, soft; hands cold; the rest of the surface of the body warm, and covered with perspiration; bowels open; urine scanty and high coloured. Tongue moist, covered with a creamy fur; constant tremors of the hands; eyes restless; manner quick and hurried. She answers questions pretty sensibly, but in an abrupt manner; and evidently makes a great effort to appear composed.

Her friends state that her affairs have been much embarrassed for several months, and that in consequence she has drank more than usual, but not so much as to make her intoxicated. Five days ago she began to lose her appetite, and felt chilly; she became low spirited; started in her sleep at night and complained of a load at her heart. As these symptoms became worse, and as she had had no sleep for the last two nights, she was brought to the hospital. She was immediately sent to bed, and ordered the following:—

℞ Morphiæ acet., gr. ¼; Sp. æther. sulph. c., ʒ ss; Sp. lavand. c., ʒj; Mist. camph., ℥ viss.; 2dis horis. A mutton chop, and strong beef-tea.

May 21. Did not sleep last night, but frequently tried to get out of bed, though easily persuaded to lie down again; was constantly saying she saw rats and other dark-coloured objects running about the ward, and over her bed. Pulse now 112, soft; tongue tremulous, white, and moist; surface of the body warm, and perspiring properly, with the exception of the hands and feet, which are cold; tremors of the hands increased. She is constantly busy arranging some part of the bed-clothes. Answers rationally, but immediately after begins talking of her affairs.

Omit. haust.; R. Tinct. opii. m. xl; Aq. menth. pip., ℥ss., 2dis horis donec somnus erit. A bottle of stout.

22. She continued much in the same condition until yesterday evening, when, having taken at intervals ʒ iij. ℈ ij. of laudanum, she fell into a quiet slumber which lasted for two hours, when she awoke much refreshed, and comparatively calm. She continued to sleep at intervals through the night. She is now much less hurried; answers questions without such an apparent effort. The tremors have abated, but not disappeared. Pulse 96; hands warmer.

R. Tinct. opii, Sp. æther. sulph. c., Sp. lavand. c., āā m. xxx; Mist. camph., ℥ xiss, ter in die. Strong beef tea.

23. Slept well last night, had no dreams; manner composed; tongue cleaner; pulse 88, fuller.

Perstat.

28. Continued improving until last night, when she became restless, and again saw frightful objects; her pulse also became more frequent. Two ounces of brandy were administered; she soon became composed, and slept through most of the night without dreams.

Perst. in mist. bis die tantum., Perst. in usu sp. vin. gal. vespere.

June 2. She again had a return of the restlessness and confusion last night; and imagined she saw objects flitting about the ward. Her manner is quicker; there is a slight return of the tremors; pulse 90, soft; tongue white.

Perst. in mist. c. tinct. opii, m. xiv., omni nocte; c. tinct. opii, m. xx., omne mane.

5. She is now quite calm; has no tremors; sleeps well at night; does not dream or start. Pulse 76, natural as to volume; tongue quite clean; appetite good; bowels regular.

Omit. mist.; R. Tinct. hyosciam., m. xxx; Sp. æther. nit., ʒj; Sp. æther. sulph., m. xx; Mist. camph. ℥ x., bis die.

9 Left the hospital *recovered.*

REMARKS.

Two forms of delirium tremens are allowed to exist by most writers on this subject: one, which is rare, and is connected more immediately with the symptoms of intoxication, being characterised by redness of the face, suffusion of the eyes, a full pulse, and irritability of temper, no doubt depending on excited vascular action in the membranes of the brain. The other, and more frequent form, being indirectly produced by drunkenness, and characterised by a cool, perspiring skin; small and soft pulse; and a busy, but not furious delirium; this is called, par excellence, "True Delirium Tremens," and was the form with which our patient was attacked.

The cause of the disease was doubtless the long continued abuse of spirituous drinks, and in the majority of cases the same cause is acknowledged; and it is not at all necessary that the patients should become intoxicated. Dr. Watson in his lectures relates the case of a porter at St. Bartholomew's, who was always able to do his duty, but was constantly fuddled; he had repeated attacks, and at last died. It may also follow an excessive debauch in those who are generally temperate. The delirium traumaticum of surgeons is the same complaint: and very similar symptoms are frequently seen in those who are reduced by frequent bloodlettings, or other profuse evacuations.

The symptoms in the present case may be conveniently divided into two stages: the first being that which occurred before her admission; in fact, at the onset medical advice is seldom sought. It commenced with diminished temperature of the surface of the body, loathing of food, frightful dreams, frequent perspirations, depression of spirits, and oppression at the præcordia. On admission the second stage had fully commenced: her manner was anxious, hurried, and restless; pulse quick and small; hands and feet cold; the rest of the body warm and perspiring; countenance pale and anxious; there was much mental delusion, as evinced by her constantly trying to get out of bed, although she was easily restrained; she also imagined the presence of frightful objects (this symptom seems to have given origin to the word "blue devils," from the objects appearing always of a dark colour); there was total deprivation of sleep; there were tremors of the hands and tongue, which latter was much furred and moist; urine scanty; pulse soft, ranging from 100 to 120.

In a short time, by appropriate treatment, this stage was ended, and refreshing sleep obtained. But it may not be foreign to our purpose to inquire, how might this disease have ended had the second stage proceeded farther? As the irritability increased, the vital energies would have become quite depressed; the pulse would have been thready, and more frequent; there would have been coldness of the whole surface, with a clammy sweat; the tremors would have increased; at length a calm would have ensued, and the patient would soon have expired.

A guarded prognosis was given at the commencement on account of the severity of the symptoms; but from the fact of its being a first attack, and her constitution being yet unbroken, it was much more favourable than it would have been had she been broken in constitution, or had the disease occurred frequently before.

Diagnosis.—The former and rarer form of delirium tremens differs from the present case in being caused more directly by the abuse of stimulants; in it also the pulse is stronger; the face more flushed; skin hotter; delusions more violent; and tongue drier and redder. Phrenitis also differs from it in the pulse being hard and resisting; the tongue parched and rough; the face red; the skin dry; in the presence of headache, and the absence of tremors. The delirium of fever comes on late in the disease; is of a low and muttering kind, attended with picking at the bedclothes, and subsultus tendinum.

Pathology.—Very little has been made out satisfactorily about the morbid appearances found in those who have died of this disease, especially of its true form. Perhaps serous effusion within the cranium is the most common appearance, though frequently nothing at all morbid can be detected.

Dr. Craigie, in his "Practice of Physic" (art. Brain Fever of Drunkards), enumerates the following as most usual:—"Effusion of serum in the sub-arachnoid cellular tissue. The vessels of the pia mater distended with dark-coloured blood. The sinuses of the brain loaded with dark, semi-fluid blood. The ventricles distended with serum. The lungs congested. The right chambers of the heart quite full; the left perfectly empty. Steatomatous deposits in the coats of the arteries. The mucous membrane of the stomach thickened, or softened. The liver and kidneys variously diseased." But, perhaps, these appearances ought more properly to be referred to the continued action of the stimulus on the various organs, than to be considered closely connected with the disease in question. In fact, we constantly find all these appearances in drunkards dying of other diseases than delirium tremens; and, indeed, in those who die of it, we frequently do not find any of these appearances.

This uncertainty with regard to the morbid appearances makes the nature of the disease more difficult to be understood, or expressed. Perhaps Dr. Watson's definition is the best: he calls it "nervous irritation," and perhaps this also produces, and is combined with, exhaustion. The action of alcohol on the system has been well described by Dr. Craigie; and perhaps I may be allowed to sketch a slight outline of his views. He says (op. cit.), that on the introduction of alcohol into the stomach it immediately coagulates all the albuminous articles of food, thus of course rendering them more difficult of solution by the gastric fluid. It also accumulates the blood in the gastric vessels, and then causes it to stagnate, producing first irritation, then languor and relaxation in the villous membrane. It next becomes absorbed by the veins, which concur to form the portal vein, traverses thence to the liver, where it produces congestion, and impedes the secretion of its proper fluid. It next passes through the vena cava ascendens, into the right side of the heart, then along the pulmonary artery into the lungs; here it retards the flow of blood, and produces temporary congestion, both in the pulmonary capillaries, and in the bronchial arteries; thus inducing chronic cough and asthma, and, of course, from the imperfect arterialisation and stagnation of the blood in the lungs, the meningeal and cerebral vessels are constantly overloaded with venous, and imperfectly aerated blood; and at last, from the constant congestion, it produces irritation. The alcohol has also an immediate effect on the nervous system, which, however, is in more direct connexion with the symptoms of intoxication. But Dr. Craigie seems to argue that this state of congestion in the vessels of the brain is the immediate and exciting cause of delirium tremens, and that, therefore, the congestion should first be removed by bloodletting, and other evacuations, before the irritation is attempted to be allayed. But, with all due respect to so great an authority, I must say that this is not the plan which I have usually seen adopted. Perhaps his arguments may be better suited to the first and rarer form of the disease, for there, in fact, we have evident signs of congestion in the red face, ferretty eyes, hotter skin, quicker pulse, and greater wildness and violence of the delirium.

The *treatment* of this disease must be guided by our diagnosis in the outset. If we conclude that the affection is the first form, moderate local depletion must be employed, by leeches or cupping to the head, assisted by cold, as often as the head becomes hotter than natural; purgatives, combined with cordials, are especially useful; antispasmodics and stimulants must also be employed. In the second or true form, opium must be looked upon as the sheet anchor. We may perhaps commence with a purgative, if there be any congestion about the liver; and then, as the great indication is to calm the nervous irritation and procure sleep (for if the patient be without sleep for many days, he will be sure to die), we must give one of the forms of opium, at short intervals, and perhaps we may increase the dose at the patient's usual hour of sleep. Opiate enemata are very highly spoken of by Dr. Graves, of Dublin (Clinical Medicine, art. Sleeplessness). He says that frequently, in other diseases besides delirium tremens, when much opium has been taken by the mouth, it has soon lost its accustomed effect, and even large doses have fail he has then

ordered an enema, with a small quantity only of laudanum, and it has soon been followed by refreshing sleep. The warm bath may also assist in allaying the nervous irritation. If the digestive organs are not disordered, good nutritious drinks may be given; but they will mostly partake of the general exhaustion of the system, and the patient will then require some of his accustomed stimulus; in fact, it is curious to see how materially this assists the opium in its action, and how soon the patient will sleep after its exhibition. Dr. Nairne mentioned having treated a gentleman twice for this disease; each time he tried the effect of opium alone, but found that it produced no effect, until a glass of brandy-and-water was added about the patient's usual hour for sleep, the consequence then was that he soon fell into a refreshing slumber, from which he awoke with all the symptoms relieved. Physical coercion is seldom employed in this disease, because it still further increases the irritation, and exhausts the patient's strength; it is indeed very seldom necessary, as the delirium is not furious, and the patient may be easily persuaded by a good-tempered assistant.

Our patient, in the present case, seemed clearly to labour under the second form of the complaint; she was therefore ordered a quarter of a grain of acetate of morphia in some diffusible stimulus; this, however, produced no beneficial effect. Laudanum was then ordered to be given in large doses every second hour until sleep should be obtained; but she took nearly half an ounce of this before any effect was observed. It was curious to notice the marked alteration in her symptoms after a few hours sleep; she seemed, in fact, comparatively well. She afterwards took the laudanum in smaller quantities, and at longer intervals, and she continued improving, until one evening she had a recurrence of her former delirium, which was immediately put a stop to by a dose of brandy. This stimulus was continued for a few evenings, with an increased quantity of laudanum; and it was gradually discontinued as she was found able to bear its removal. She had perfectly recovered in less than three weeks.

REVIEWS.

Practical Notes on Insanity. By JOHN BURDETT STEWARD, M.D., Fellow of the Royal College of Physicians, London, &c. &c. 1845.

Few medical subjects excite such general interest as the care and treatment of the insane; and to none has the public attention of late years been so much directed.

At no very distant period, asylums for the reception of lunatics were—with some honourable exceptions—little better than prisons, in which, if the unhappy patients were prevented from injuring themselves and others, the object of their confinement was sufficiently fulfilled, while the harsh treatment which they experienced tended to retard, rather than promote, their recovery. During the present century, however, a vast change has taken place in the management of the insane, and most successful, in many respects, have been the efforts to ameliorate their condition. Measures have passed the legislature to provide for the better regulation and superintendence of lunatic asylums; and the commissioners, appointed to visit those institutions, have published a report, abounding in just views, and statistical information.

This important change is chiefly owing to the advancement of medical science; for while the general management of the insane may and should be controlled by acts of Parliament, their restoration to health must depend upon the judgment and skill of those to whose care they are intrusted.

It is, from men who have had personal experience in the treatment of Insanity, that we may expect to obtain such information respecting its nature and causes, as will lead to sound views on the curative means to be employed in its various phases. Such is the author of the work before us.

For ten years Dr. Steward discharged the duties of physician to the Droitwich Lunatic Asylum, of which favourable mention is made by the Metropolitan Commissioners; and his "Practical Notes on Insanity" are the produce of their author's own investigations—of the inquiries of one, who has taken the trouble of thinking for himself.

Dr. Steward justly regards "the evident loss of self-control" as the symptom of insanity or mania—for he uses these terms synonymously—which peculiarly distinguishes it from mere eccentricity. And he enumerates three species of the disorder.

1st. *Idiopathic insanity*, or the disease in its pure form, without derangement of general health, functional impairment, or disease of any organ. Under this head are comprehended all those cases which solely arise from mental emotions.

In speaking of the *absence of functional impairment*, our author, of course, means to except the action of the nervous system, for in every mental disorder there must be a corresponding movement in the nervous matter. In this kind of insanity, the passions are the exciting cause of the malady. The nervous current is disturbed by impressions that may be conducive to joy, sorrow, ambition, or despair; and the reason, the judgment, and the imagination, are consequently perverted. But the agitation of the nervous matter is temporary, and merely such as may be required for the extraordinary discharge of its functions. There is no permanent disorganisation, unless the attack be so long continued, or so often repeated, as to create an artificial habit; for then anxiety of mind may induce disease of the brain, upon the same principle that over-excitement of the circulation may terminate in disease of the heart.

In that event, the affection would lapse into the third species, which we are about to mention. Our author's second species, which he calls *symptomatic insanity*, comprises those cases which are "apparently dependent upon, or at least are accompanied by derangement of the general health;" while in the third species the state of the intellect, is connected with a morbid change, either in the brain or in some other organ.

This arrangement at once developes Dr. Steward's general views. Founded upon pathology, it leads to sound practice; and accordingly, in the remarks on the curability, symptoms, exciting causes, and treatment of insanity, we find the constant object of Dr Steward's investigations to be not how to keep, but how to cure the invalid.

To give anything like an account of the contents of this volume would exceed our limits in this notice. We shall, therefore, select a few passages, which particularly claim attention. The first of these is contained in the chapter on Criminal Insanity, wherein after remarking that nothing is more easily feigned than insanity, Dr. Steward thus proceeds.—

"It is not a few, nor even a succession of eccentric acts, that ought to be allowed as proof of the existence of that state of mind, which destroys the power of self-control, and relieves the individual from his responsibility as a free and accountable being.

"To adopt the principle, by some advocated, that, in certain cases, the act alone is proof of insanity, would offer an immunity for crime, calculated to shake the very basis of society; since, upon such a principle, the inference is forced upon us, that the more dreadful the crime the stronger evidence it affords of infirmity of mind, and the more convincing is the conclusion that no man in his senses could have committed it.

"The same individual who would have passed through life unobnoxious and unnoticed, by one act of violence becomes an object of attention. His friends, anxious to save him from the consequences, and themselves from the disgrace, review with deep anxiety his past life, in the natural hope of drawing from it some explanation and excuse for his crime. Every previous act, which, in its occurrence, excited neither anxiety nor alarm, is examined and discussed.

"One only object in view, one animus exciting, each fact is tinctured by preconceptions. The object wished is first assumed, and facts are sought to justify it. All in favour are adopted, all in contradiction rejected; and not unfrequently it has happened that evidence has been admitted as establishing the plea of insanity, which, as regarded the same individual under different circumstances, would have been condemned, and justly too, as wholly insufficient."

We wish that judges and jurymen would cogitate on this. Independently of the broad distinction between eccentricity and insanity, which our author has so clearly defined; it is a serious question, whether such reputed lunatics as have sufficient sense to be controlled by fear and other moral restraints, be not to a certain extent morally responsible; and if this be admitted, whether their punishment would not deter others in a like condition from committing similar crimes. We allude here to those half-witted persons, who, while unscrupulously injuring any one whom they may imagine to have been an obstacle to their wishes or designs, yet well know how to take care of themselves in the ordinary affairs of life, and not, of course, to complete maniacs.

The following passage, on the necessity of restraint, may be found in the tenth chapter:—

"In concluding this part of my subject I may, I hope, be permitted to add, as marking more clearly than mere words could do, my favourable opinion of the non-restraint system—which, as would appear by the visitors' reports, since 1833 it had been my most anxious and constant object to advance—that when the commissioners under the New Act visited the Droitwich Asylum, wholly without notice, at half-past 11 o'clock, a.m., on the 16th of September, 1842, there were, out of eighty-six patients, only two—both males—under restraint; one of whom had committed murder, and was, if not restrained, constantly attacking his fellow patients; and the other, a person equally dangerous and unruly. The restraint was simply the belt and runners. I wish further to observe, that although the experience of more than ten years—with, as I have said, the constant object in view, of superseding, as far as possible, the necessity for restraint—does not enable me to agree with those who maintain that restraint is *never* necessary, still I feel no hesitation in declaring my belief that, with proper rooms and fittings, the only plea that can warrant its use, is the personal safety of the lunatic himself, or the absolute necessity of imposing it, to prevent the commission of crime."

The idea of liberty is so imposing, and the spectacle exhibited by a wretched sufferer vainly endeavouring to emancipate himself from his bonds is so painful, that we are not surprised at the enthusiasm with which the non-restraint system has been very generally received by the public; but with many advantages, it is often attended with great danger to the patient as well as to those about him. In numerous instances it is found impossible to dispense with all restraint, and then the question lies between solitary confinement in a room, and confinement of the limbs alone, while the patient may have the benefit of fresh air and the society of others. With a heartfelt wish that all restraint could be avoided under all circumstances, we are compelled to agree with Dr. Steward that in some cases, although happily these are comparatively rare, it is absolutely required for the well-being of the individual himself as well as for the safety of his companions and attendants; and for ordinary purposes we think seclusion not the best means that can be adopted. "Nothing," says Dr. Steward, "is more likely to confirm insanity, or even, as facts have shown, to produce it, than long seclusion. Fits of anger and violence must be met by short periods of seclusion; but the confinement should never be prolonged beyond returning calmness, or a promise to forbear similar conduct." Dr. Steward's observations on the association of the insane with each other, and on their employments and amusements, are good. He thinks that when judiciously managed these resources are of the greatest utility, both in rendering the present condition happier, and in promoting the cure of the malady; and he says that, "There is no amusement or occupation which, to those who are well enough to enjoy it, ought to be denied." Amusement, indeed, as may be readily imagined, is not always practicable; for we well know that when the mind of a sane person is either weakened by illness, or very strongly bent upon one absorbing subject, nothing is more difficult than to divert it; and how much greater must be the difficulty with the insane, of whose disorder in many instances, a solitary, but powerful mental impression may have been the cause? There is, however, no point connected with

the cure of lunatics more important than this; for while occupations properly selected may be most beneficial to the curable, by withdrawing the mind from morbid trains of thought, and by improving the general health—in the incurable cases they break through the monotony of a life, that under the most favourable circumstances can admit of comparatively few enjoyments, and may stop the further progress of a disease which the best efforts of humanity and science fail to eradicate.

In closing Dr. Steward's work, we have to express a favourable opinion of its tendency and doctrines. Dr. Steward looks at the subject in the right direction, and with the eye of a man who has studied human nature as well as pathology. In perusing his "*notes*," we have been impressed by the excellent spirit they breathe, and the many important suggestions they contain.

TO CORRESPONDENTS.

Chirurgus.—*The degree in question is sufficiently respectable.*

A Subscriber *does not say what classical examination he means. The Latin examination of the Society of Apothecaries is in future to form part of their general examination.*

Chirurgus (Wainfleet)—*The terms of admission to the society named are a payment of one guinea annually.*

Mr. Redstone's *request shall be attended to.*

A Subscriber to the Medical Times.—*We believe our correspondent to be entitled to payment.*

Mr. Henry Smith, *house-surgeon of King's College Hospital, has sent us the following not very common case:—*

I was called up in the night of Tuesday, May 12th, to a man who had received an injury of the right arm. Before coming to this hospital he had been seen by a neighbouring practitioner, who stated that it was a dislocation of the elbow, and had used means to put right the supposed accident. On examining his arm, I, without any difficulty, discovered a fracture of the humerus, about two inches above the condyles. On inquiring into the cause of the accident, I found it had taken place in this curious manner. My patient and another man were testing their muscular strength, by endeavouring to force down each other's arm, the hands being clasped together, and the elbows resting upon a table. The former having nearly forced down his antagonist's arm, made a sudden exertion to do so effectually, and thus put the muscles of his arm into powerful action. He instantly heard a snap, and exclaimed that a bone was broken, but did not know at first whose arm was injured. He is a German, of twenty-five years of age, of muscular frame, has never had syphilis, or laboured under any debilitating complaint, and is in excellent health.

Medico-Chirurgus *writes us a long article on the Sydenham Society. He affirms that, while defending Paulus Ægineta from a "prejudiced and mistaken judgment," our article on the subject "leaves the Society just where it found it." "That body deserves much credit," he continues, "for the attention it calls to the state of medicine in past centuries; for it is something in this age to teach our great guns of medicine what is already known. It saves us a multitude of discoveries, and, what is worse, a multitude of profitless discussions as to who—Dr. H., or Dr. Somebody earlier—has the priority."* "*It is a* Medical Society of Antiquaries," *he says, "and on that score, and that alone, deserves support. It never was meant to come into competition with modern authors, or publishers; and if it try, must meet a signal failure. People say that it is not practical enough; that it's a curiosity shop, a joint stock publishing company of Dryasdusts. But practical usefulness is not its business. Your own Journal forms the* practical Sydenham Society *of the Profession. Your two large volumes—which contain almost as much, both in practice and theory, as the Sydenham Society could furnish for half-a-dozen years subscription—exhaust all that is wanted to be known in the scientific currency of the twelve months. The Sydenham Society has other purposes, and these it fulfils." Our correspondent proceeds to shew the uselessness of republishing scarce books, "which without the aid of the Society could only be met with," he sneeringly adds, "on the ordinary old book-stalls;" and he insists that if there were "no jobbing in the purchase of the paper, in the payment of the printers, and in the publishing department generally," the antiquarian portion of the profession would be largely indebted to the discriminatory genius and activity of the council and secretary. To the latter he pays a high encomium as meriting fairly the handsome remuneration bestowed on him, and as thus carrying out cleverly the real object of the society. Want of space compels us to content ourselves with this brief abstract of our correspondent's letter—in reference to which we have only to say, that we see nothing to retract in our former article on the subject.*

An Edinburgh M.D. *is thanked for his article, which we decline, however, on account of the personalities that are incorporated in it. Our opinions and his on the character and science of Professor Simpson differ* toto cœlo. *He is one of the few remaining lights of the old University.*

The Poisoning Case at the University College.—*In reference to several communications we have received on this subject, we have to say that we know of nothing to revoke in the comments we have made on it. We affix no blame to the house-physician, for, as his title signifies, he was in no way responsible for it. The responsibility lies with the higher medical and surgical officers of the establishment, who knew of the existence of the system—who were daily admonished of its evident dangers—and who took no one step for a change. It is a melancholy exemplification of a system almost universally defective.*

Dr. Haygarth writes:—"Considering society as divisible into three classes, would it not be advisable for the general practitioner to regulate his charges upon the following principle: First class (gentry), for three to five visits, one guinea; second class (trades), for eight visits, one guinea; third class (artisans), for twelve visits, one guinea. The medicines in all cases to be supplied by the medical attendant, at their true cost, without profit. The latter condition exercises an all-important influence upon the general interests of the profession

Mr. Coles *writes us a reply to our review of his book. His reference to the "eminent physician," Procrustes, was meant for a joke—though in that way it escaped our powers of recognition.* Mr. C. *insists further, by a reference to Hippocrates' work, "De aere locis et aquis," Foes. fol.* 293, *that the women of the Sauromatæ—a Scythian tribe—lost their right breasts by the early application of heated brass to that region.* Mr. Coles *is mistaken in supposing that all authors treat the Amazons as Scythians. Diodorus speaks of them as an African nation."*

A Practising Apothecary *writes a long letter to show the power and privileges of the Druggists to play the part of Medical Practitioners. He insists also, in modified terms, on their competency for that task, and quotes the Lancet recommendation often given to druggists, and persons similarly situated, to practise in defiance of the act of* 1815. *Our own opinions on this subject are so well known, that we need only furnish this brief abstract of the letter.*

S. S. T.—*A gentleman holding such a diploma would be duly qualified. A coroner has the power of summoning any duly qualified practitioner he pleases to give evidence on an inquest.*

Vindex *tells us the qualifications of the present Apothecary of the University College. Will he tell us whether the rules of the Institution do not permit the office to be held by a student of two years' standing? Has it not been so held? Is it* not now *so held?*

B. P.—*There is no fixed number of days. There is a range of from* 259 *to* 280 *days, with exceptions, of course, outside either term. But the question is,* adhuc subjudice—*vide Dr. Rigby's Lecture in our last volume.*

Mr. Ferrand's *case does not, we think, need the extended notice he seeks for it. We are, besides, anxious to avoid noticing subjects that belong properly to other journals.*

Mr. Self *is thanked for the notice from the* John Bull. *We are glad to see the able pen of that journal devoted to the service of the medical public.*

A Student *is informed that this is the 7th number of the present volume. The former numbers may be obtained by early application.*

B. Bath.—*We have been startled with some of the theories of Swedenborg on physiological subjects; but we cannot entertain any discussion which includes reference to his theological opinions.*

Medicus *can obtain the* Pharmaceutical Number *he wishes by sending postage stamps for the amount to the publisher.*

The numerous Correspondents who have addressed us on the temporary suspension of the "*valuable*" *Lectures of Mr. Startin and Dr. Costello, are assured that we estimate their importance not less highly than the most encomiastic of our readers, and that we shall not fail to do our best to produce them as frequently as possible. The Lectures of Dr. Rigby, which a* "Country Practitioner of Forty Years' Experience" *declares to be the best ever published on Midwifery, shall not be overlooked. We shall continue them fortnightly.* Perhaps this occasion may not be unsuited for the observation that the Lectures of the present volume (which cost our Subscribers but half-a-guinea) would not be purchased, if in separate works, at much less than three or four guineas.

The Pharmaceutical Number *of the* Medical Times *for May, is now ready, and contains twenty-four closely-printed pages of the most important matter to the chemist, pharmaceutist, and general practitioner. Price* 5d; *Stamped* 6d. *J. A. Carfrae, Essex-street, Strand.*

THE MEDICAL TIMES *is the only Medical Journal published at its own Office, and which is free from the control of all Booksellers and Publishers. Gentlemen may procure it by an order on any Newsman or Bookseller, or it will be sent direct from the Office of the Medical Times to Annual Subscribers sending by a Post-office order, directed James Angerstein Carfrae, or an order on some party in town, One Guinea IN ADVANCE, which will free them for twelve months. Half-Yearly Subscription,* 13s.; *Quarterly,* 6s. 6d.

THE MEDICAL TIMES.

SATURDAY, MAY 23, 1846.

> Yet let me flap this bug with gilded wings—
> This painted child of dirt—that stinks and stings.
> POPE.

THE duty of unveiling fraud or duplicity is one of the most uninviting which an editor can be required to perform. Whatever may be thought of it by the reader, whose heart, perhaps, palpitates with indignation as he scans the reproving page, it is certain than the mind of a writer returns with disgust to the consideration, and that his hand traces with reluctance the records of guilt. It is an irksome task that we cannot escape, if we would, and which we dare not, if we could. At the head of a journal influential beyond our most sanguine anticipations, there come to us claims which we cannot evade—duties we dare not abandon—responsibilities from which we cannot retreat—functions we must execute—and, as we have resolved never to be wanting in any act that may conduce to the benefit of our Profession, even at the serious risk of giving notoriety to scandalousness, we feel it incumbent on us this week to make an exposure of a mean artifice of a mischievous malice which appeared last week in the columns of another journal.

The members of the National Association are aware that, in the last number of the Transactions

of that body, the following notice appeared in the last page:—

"In order to guard against any misapprehension, the committee desire distinctly to state that the proposed National Institute in Medicine, Surgery, and Midwifery, is not intended to merge the three branches of the Medical Profession into one institution, or to form what has been termed a "one faculty" of medicine for the entire Profession, to the disparagement or subversion of the existing colleges.

"*Whatever the future arrangements of the Medical Profession in this country may be*, the immediate duty of the Practitioners in Medicine, Surgery, and Midwifery is to complete and consolidate their own organisation; and to effect this object *every duly qualified Practitioner* is admissible for enrolment in the proposed National Institute."

This paragraph was clearly inserted to allay any hostile feeling that may exist, to promote union, and to draw together into one great movement the greatest possible number of our professional brethren. Conscious that nothing but unanimity could ensure the success of their plan, the committee wisely determined to admit *any legitimate Medical Practitioner, no matter how or where qualified*, into their new Institute. The announcement was no less liberal than it was wise, and, we had thought, would have disarmed the malevolence of the most suspicious mind. As the event has proved, however, there are depths of malignity which we have not yet sounded. The acts of some individuals defy all calculation—their effrontery exceeds credibility, as their viciousness surpasses every rule of ordinary experience; they must be dealt with as moral monsters, having habits and instincts of their own, whose psychology is an incomprehensible aggregation of contradictions, displaying at the same time, and in the same act, the imbecility of the sheep, the obstinacy of the mule, and the cunning of the serpent. These are fine subjects for a moral anatomy; very apt, however, to become putrescent before their mysterious organisation has been laid bare by the critic's knife. But let us leave them to proceed to our task.

Our lugubrious contemporary—whose weekly effusion is always either a prophecy without fulfilment, or a lamentation without *external* cause—finding no opportunity, last week, for indulging in his lachrymose propensity, must, perforce, make one, and hence contrived to convert the announcement we have quoted into a subject for his "*melancholy reflections*." A *true statement* of the case would not, of course, have answered this end, so his usual resource in every dilemma was necessarily resorted to. Notwithstanding the proverbial and often avowed stolidity of our contemporary in matters of this nature, we are very sure that he understands the nature of a "*mistake*" as well as other men, and that a garbled quotation emphatically printed, so as to furnish salient points for deceitful comments, is an unquestionable falsehood in his opinion as well as in our own. The attempt to deceive is all that is necessary to constitute a falsehood; and the *literal* truth, adroitly used, is often the most ready means of insinuating a substantial falsity.

Hence it was, that our cotemporary found it desirable to publish only the *first* paragraph of the announcement alluded to; and to suppress the second, which clearly anticipated some fundamental change in the arrangements of the Profession at a future period. The editor—apparently suffering under his periodical fit of monomania—is greatly vexed that the Committee of the National Association should explicitly declare that they do not intend to establish a "One Faculty," but rather "*complete and consolidate their own organisation.*" They knew that a "*One* Faculty" meant anything or nothing; that no two men in the Profession were precisely agreed upon the meaning of the term, that it was nothing more than a vague and chimerical project, as it had been advocated by shallow and headstrong agitators—that to them the "*one*"-ness presupposed the absence of subordinate parts—that, as a governing body, for the Profession, it was a mere nebulous phantom, comparable only to the poet's description of death:—

"What seemed his head
The likeness of a kingly crown had on."

Rejecting, then, the terms of empty phrasemongers, they seize upon things, and they resolve to consolidate their own organisation." This is an object both tangible and attainable, and they wisely determine to attempt this, and this alone.

If a "One Faculty," taken in the more reasonable sense which the more enlightened can attach to it, be considered a more extensive measure, surely this is the best means of eventually attaining it. This is clearly the opinion of the Committee; and we shall act prudently and politically if we accept the present plan as a means for accomplishing yet greater advantages. The only difference between the parties is this: that the Committee are seeking to establish a means for an end—less practicable people would clutch the end without the means. Like Milo, we shall yet see such persons' hands wedged in the trunk they are striving to rive. Such folly calls down its own punishment.

Our contemporary thus comments on the mare's nest that he has been so fortunate as to discover: "What, then, is to be the 'National Institute in Medicine, Surgery, and Midwifery?' But, after all that has transpired, the subject is too pregnant with melancholy reflections, &c.:" but we refrain from transcribing any more from these "melancholy reflections," lest we should touch the hearts of our readers with more laughter than becomes the occasion. The editor is doubtless pregnant with many "melancholy reflections," which the history of medical reform has begotten in him. A character irrecoverable, an influence blighted, professions derided, a name not honoured, his word discredited, his supplications spurned, his wrath ridiculed, his plots frustrated, his duplicity unmasked, his friends perfidious, his enemies compassionate: Alas! here, indeed, is matter enough to afflict even a Democritus with "melancholy reflections!" We recommend his friends to look well to him, for these same "melancholy reflections" may settle into an incurable fatuity, of which we have recently observed several very ominous symptoms. If they desire to consult us upon his case, we can inform them that we are in possession of a balm that would "lay a flattering unction to his soul." No time, however, should be lost—the fitful fever is rapidly changing its character—the stage of exacerbation is subsiding into the collapse of despondency—the ravings of vituperation are dwindling into the whining accents of drivelling imbecility. We can imagine the unfortunate gentleman sitting solitarily in a dark corner of his chamber, with his head upon his hands, and his eyelids drooping over his passionless eyes, sighing piteously over his "melancholy reflections." "Canst thou not minister to a mind diseased?" We reply *yes!* Remorse hath a remedy—retirement and repentance. We earnestly enjoin them. With the public there may be some uses in him: for the profession there are emphatically none.

Bonum est fugienda aspicere alieno in malo.
PUBL. SYRIUS.

WE observed, in our last discourse on professional mendicancy, how often our charitableness had been assailed by adventurers unworthy of it. It may appear to some to be a subject hardly deserving consideration or comment; and yet it occurs to us to think that it merits at least some notice. It is an abuse, and therefore calls for correction; it is chiefly practised upon the inexperienced, who consequently cannot fail to be advantaged by the grave suggestions of their senior sufferers—it is a sort of "man-trap" in our professional path, and though we may not be able to utterly drive it from our presence, at least we may avoid the punishment of its gripe.

The system of professional begging we allude to is, in fact, a regular species of quackery—a scheme of deception and hypocrisy as organised and well constituted as any balm, balsam, pill, or potion treachery that is, or ever has been, the opprobrium of a civilised community.

A certain information of which we are in possession gives us the assurance that there is a sort of mendicant club, or council of beggary, for the express training of candidates for the degree of doctor in distress. Experienced officers, whose long practice in the art of "humbly petitioning," and whose skill in designing and disguising, renders them authorities in the "gentle craft," occupy the responsible position of tutors to such as may be in *statu pupillari*. These professors, as they are termed, have themselves left off trade, or at most pursue it only very occasionally, and in a very quiet, genteel sort of way. They seldom go from home on an expedition of plunder, or solicit assistance in *propria persona*, having already so well acquainted the profession with their physiognomies as to render personal applications rather hazardous. To avoid, therefore, the unpleasantness of discovery, and the probable deserts that would follow it, they find representatives in autograph letters, printed circulars, and titles of books that are about to be published, but are just now delayed for want of means.

A common trick with an old sinner of this sort is to feign a lady's hand, and announce himself to you, in a neatly-expressed matter, as the widow of a physician or surgeon, left with no more available capital than sufficed to bury her husband and buy mourning for her children. You are appealed to with a passion and pathos that would be very unnecessary if the statement were true; and are apprised that the smallest donation will be thankfully received, and may be transmitted either to the petitioner, or to some one of the fraternity, who is signalised as the Rev. Mr. Somebody.

Another plan is, for one of the tribe we speak of to address you, *bona fide*, in his own behalf, informing you that he was once in competent circumstances, but a law-suit, a loan to a faithless friend, or losses by fire, fraud, or ill-fortune, have reduced him, and a once happy family (a good round number, of course), to comparative destitution. Business is at a stand still, and beggary—stark-staring beggary—is right before him. He not only tells you that he has seen better days, but suggests the probability of being a much better man than you take him for, in proof whereof he strings as many letters after his name as would spell all the lingo in the war song of a Chippeway chief. These letters are about as interpretable as the designs on an Egyptian mummy, and have as much to do with reality as with the man in the moon. Besides this regiment of emblematics, there is generally subscribed, author of this, that

and the other, with a flourish of *et ceteras* at the end, which seem to signify that there are divers other points of consequence too numerous to mention. Of course, the whole affair is fiction—the works paraded never having seen daylight, and not being very likely ever to get a glance of it.

The same may be said of the prospectus and title-page of a work about to be issued, only wanting a little of the needful, which you are politely invited to supply, with the assurance that you will certainly either get it back again, or get a book in its place. We have ourselves been more than once tricked with this imposture, all our gainings being the getting laughed at.

The gentry we speak of having followed the practice of itinerant mendicancy sufficiently long to make its continuance either doubtful or dangerous, have acquired in that space of time knowledge enough of human weakness, and of the best methods of assailing it, to constitute them authorities in the art of drawing upon charitable bounty. The *modus operandi* they communicate to any aspirant to polite beggary, for certain considerations, present or prospective, varying with the condition of the parties interested. Sometimes the fee-total is far from inconsiderable, when much drilling is needed; and conversely, the rate of charge is proportionally low. Testimonials and certificates are costly in the direct ratio of their fulness of expression and fertility in falsehood. An indenture of apprenticeship, with a commentary on the uniform good conduct of the possessor, fetches one price—a letter, stating that the individual had deported himself with the utmost propriety, and evinced a very competent knowledge of disease, and its treatment, whilst assistant to the donor, fetches another—certificates of having attended lectures that have never been delivered, and of having obtained the esteem of lecturers that have never lived, have various degrees of value attached to them, according as they are made to resemble reality, and promise to answer the best wishes of the possessor—imaginary medical diplomas, and fantastic pieces of parchment, idealising fellowships and memberships of various learned societies, and garnished with a suitable appendage of hieroglyphical names, are considered the most costly documents of the whole.

Taught a certain decisive, yet deferential, behaviour; ground into a certain freedom in technical garrulity; and guarded with paper, or parchment, testifying to moral goodness or intellectual greatness, the protégé of the class we have described is deemed fit for his mission. And, in fact, he is, for there is such an off-hand, easy, likely look about him, and such seeming truth and sincerity in the tale he tells, that to detect the deception is often no trifling task. We have repeatedly listened to the tale of woe, told with just the fluency a man would have who was experimentally familiar with the sorrows he was reciting, and have been very nearly persuaded into the belief of it, before its falsehood was revealed by a more searching scrutiny. It is not long since a candidate for our charity waited upon us with all the superficial ceremony of a systematic, well-disciplined beggar. He played his part so admirably, and with so apparently unaffected a pathos, that we were inclined to believe him outright, and to relieve him according to the dictates of that first impulse of the heart, which seldom fails to favour the interests of the suppliant. He spoke so freely and undisguisedly of his professional education, and of his practice, from which he was removed by a fortuity he could not control, and seemingly courted inquiry so candidly, that to entertain a suspicion of him appeared to be ridiculous. An *os innominatum*, however, was lying upon the table, and, more out of pleasantry than doubt, we simply observed, "will you just describe that bone?" "With pleasure," said he, and taking it in both hands, and placing it on his head, said, he was not certain as to the exact place, but he "remembered it fitted in somewhere about there." It is not necessary that we should say he found his way out of the room unrequited for his visit.

Some little time previously, we were paid a visit by a gentleman similarly circumstanced, who, amongst other items of professional introduction, represented himself as having had a good classical education. We were not for a moment in the mood to doubt this, and familiarly talked with him upon certain subjects, literary and medical, which he rather glanced at than paused over, to discuss with us. There was a flippancy and fluency about him, and a mannerism, which were almost irresistible—perhaps most people would have hesitated to question their legitimacy, but a certain something we had learned from experience taught us the desirableness of asking still further into his character. As he had complimented himself upon his classical attainments, we thought it not uncourteous to test him on the points upon which he most prided himself. Accordingly, we modestly opened for him a page of Gregory, requesting he would give us the favour of a reading. He read, off-hand, without any respect or regard of accent or quantity; and then, at our request, translated with such an utter indifference to *literal* or *liberal meaning*, that we were constrained to stop him with an inquiry whether he could *parse* a sentence? "Certainly he could," he said, "if he could read the book, how could he fail to parse it?" This sounded like logic, but not liking to trust to it, considering the specimen we had already had, we committed to him a passage in Gregory to analyse. The first word in the sentence selected, was, *Jam*—we asked him its meaning—that of course did not signify; we asked him what part of speech it was; he said, a *verb*—"conjugate it," said we, "with pleasure," said he, and forthwith, he started off with "*Jam, Jas, Jat.*" It was impossible to be angry with the man, for he really conducted himself with the easy politeness of a gentleman out of place; but we certainly hesitated to befriend him as we would have befriended a professional brother similarly circumstanced. A smart, fashionable, fluent fellow, whose looks betokened much better circumstances than he said he was in, paid us a visit one day, to say how badly he was off, and how glad he would be if we would help him. He had occupied, so he said, and so said a certificate he carried with him, divers important posts in connection with a particular branch of surgery. It was with grief we saw him in such a position of distress, and would fain have relieved him on his personal application, backed as it was by testimony which looked like truth; but having been deceived aforetime, we hesitated in our charity, until having asked him, a question—only one, and that, in connection with the subject he professed to have particularly investigated—we asked him the peculiar circumstances leading to the cause of, and the best means of treating *prolapsus ani*, in the *male*, and *female*. A tyro in surgery will easily understand the drift of our inquiry, and the particular questions it involved. It might embrace a large and instructive discourse:—our gracious visitor, however, cut it short by observing, that, according to his experience, the most certain and satisfactory treatment was—*to lance the gums!*

THE UNIVERSITY COLLEGE.

We have awaited some time for an explanation of the circumstances by which Professor Sharpey was secured, by the Council of University College a high fixed pension, independently of all contingencies in reference to the success or failure of the establishment itself. The fact undoubtedly is most singular. No such provision was ever made for any other teacher. Professor Sharpey stood as good a chance as any of his brother lecturers of having an equable and goodly share of entries to his course. Up to this time it cannot be said that his services have not received—proportionately, at least—a fair and ample remuneration. Why, then, this singular arrangement, which implies on the Professor's part such grave doubts as to the stability of the school—which places the Professors, not pensioned, in so disparaged and unequal a position, and which finally presses down funds that are anything but elastic, in so weighty a fashion? We ask the question now, as we have asked it before: Are we to suppose that Professor Sharpey has used, for his own emolument, that large personal influence which should have been exercised solely for the good of the School? Has he won confidence so assiduously but to abuse it thus insidiously? If not, will he explain why this startling exception has been made in his favour? There is talk of political influence exercised to misdirect for personal advantage the funds of an educational institution: is the gossip true? If not, the activity of one noble lord, and the intrigues of a few commoners, should be satisfactorily accounted for. To leave things as they are is to throw serious discredit on the management; to place Professor Sharpey in a very invidious, not to say equivocal, position, and to make his colleagues feel that if he be not over well treated, they are indisputably over ill treated.

THE "JOBBED" EXAMINERSHIP.

The Court of Examiners of the College of Surgeons not only remains uncleared of that imputation of a bargained examinership which we deliberately brought against it, but the gentleman who is fulfilling the conditions of the bargain, and doing collegiate work at half price, weekly faces the medical students of this kingdom as their official examiner. Holding his own scientific position by the easy process of a pecuniary negociation, he sits officially to test the scientific worth of others; and the principal agent—active or passive—of a disgraceful compact, he adjudicates on the moral character of gentlemen.

Do the Council fancy that things can remain as they are? Do they think they will not be called to account for this dark transaction? They must lay no such flattering unction to their souls. The student feels the indignity of being examined under a bargained and purchased title; of standing before men who make the profits of testing his surgical competency the subject of mutual higgling and negotiation. The student feels that the place of honour is not with his examiners; that it is his hands not theirs that are unstained with low hucksterings of the emoluments of office. A gentleman and a man of science it may be, he sees in his examiners persons whose great distinction it is to derive a snug sort of traffic out of his petty fees!

Turning to the Profession generally, a worse sentiment predominates. That persons vested with the trust of testing the qualifications of future members of the Profession should meet in conclave and arrange how this man, their colleague, shall

have collegiate pay for doing no work, and how another man - one of themselves, also—shall have collegiate rank for consenting to a shabby money arrangement—that persons shall thus act in the fulfilment of high and responsible duties, is something so anomalous and monstrous, that we would believe it of no other body save the Council of the College of Surgeons. It is as wide a departure from respectability as it is gross as a dereliction of duty. The Profession expect for it a speedy explanation.

THE NATIONAL ASSOCIATION OF GENERAL PRACTITIONERS IN MEDICINE, SURGERY, AND MIDWIFERY.

This committee are busily engaged in framing a schedule for ascertaining the opinions of the members of the Profession, in reference to the establishment of the New Institute. Many of the Honorary Local Secretaries have already transmitted returns, which they have collected in anticipation of the general poll; and it is satisfactory to say that the greatest unanimity prevails in favour of the plan of the committee. There can be no doubt of final success.

There have been also numerous applications for tickets to the dinner, in honour of the venerable President of the Association, Mr. Pennington; and it is expected that the banquet will be very fully attended.

A WORD TO AUTHORS.

It is well known that the Medical Times is the only medical critic published at its own office, independently of the influence or control of any publisher or booksellers—and it is equally known that it is the only journal that is now extensively circulated throughout the Medical Profession.

To meet in some small measure the immense advantage the Medical Times thus possesses on the score of independence, the book-dealers owning other medical journals have grown into a habit of making the books they publish, both for themselves and for authors, mediums for puffing the journals so equivocally situated. Under the designation of a catalogue, pages of encomiastic trash are given to seduce readers for the unfortunate subject of bookselling speculation. This is a plan we will not uphold; and we, therefore, apprise authors, that for the future we shall not, except under special circumstances (for which they will owe us no obligation), notice any book defaced by these inappropriate mercantile puffs of publisher's journalism.

TRANSACTIONS OF LEARNED SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Meeting of May 12, 1846.

Benjamin G. Babington, M.D., F.R.S., Vice President, in the Chair.

An Account of a Case of Rupture of the Gall Bladder from external violence; by D. Maclachlan, M.D., Physician and Principal Medical Officer to the Royal Hospital, Chelsea.

The subject of this case was a pensioner, aged seventy-seven, a large and powerfully made man, but now reduced in flesh, and feeble. He had been a patient since March, 1841, for weakness of intellect, pile debility, and loss of memory. There were signs or symptoms of disease, except those referrible to the brain. On the 9th of February, in the act getting out of bed, he fell with great violence on the floor, having taken a hearty meal some hours previously.

He was insensible for a time; but rallied, when he vomited the contents of the stomach. There was epigastric tenderness; the pulse scarcely perceptible, and great prostration of strength. On the following day the belly was generally tender under pressure, partly about the iliac regions. He died forty-eight hours after the fall. On examination after death, it was found that the gall bladder had been ruptured, with copious effusion of bile into the cavity of the abdomen, producing intense peritoneal inflammation. The gall bladder was much atrophied, but there was no apparent disease of its coats. A calculus the size of a large nut was impacted in the cystic duct, just as it leaves the reservoir. The liver was healthy.

After referring to cases of a somewhat similar nature, detailed by several writers, the author concludes by observing that a practical caution may be derived from such a case, viz., the danger of employing emetics for the expulsion of biliary calculi—a practice which some physicians are in the habit of recommending. Dr. Stokes, in his "Lectures on the Theory and Practice of Medicine," states that a distinguished medical friend related to him the particulars of a case in which the gall bladder was actually ruptured after the exhibition of an emetic.

SURGICAL SOCIETY OF DUBLIN.

The Society held their last sessional meeting on Saturday evening, April 25; R. Carmichael, Esq., President of the College, in the Chair.

A letter was read from Dr. Colvan, of Armagh, on the treatment of certain cases of fistula in ano by ligature, the revival of which operation he had intended some time since to have claimed, upon the occasion of a discussion having taken place between some English surgeons, as to which of them had first made trial of the operation. When patients have a great horror of the cutting process, or cannot conveniently encounter the consequent necessary confinement to bed, Dr. Colvan observes that the ligature may, in many instances, be substituted. In three cases so circumstanced he had made a successful application of the practice, the first being that of a small farmer, who had a complete fistula situated an inch, or a little more, from the verge of the anus. A catheter wire, of the thickness of small twine, was introduced, twisted moderately tight at first, and retwisted at intervals of three or four days, for which purpose the man walked in two or three miles from the country. It was only when the wire had nearly cut its way out that he began to suffer a little from slight pain and swelling, which were removed at once by a couple of days' rest and the use of fomentations and poultices, and he has since remained well. In the second case the same proceeding was instituted, and followed towards the close by similar symptoms, which, however, as readily yielded, and the man became perfectly well. These two operations were done *fifteen years since.* The subject of the third was a female, in whom the results were the same.

Dr. Colvan at first thought his discovery a new one (as it really was to him), never having seen or heard of it, but afterwards found, on looking into Heister's old work, that an operation pretty much of the same kind had long since been performed, but which for some reason must have fallen into general disuse.

Dr. Colvan was convinced that in many cases the ligature might be used with advantage, but that it was quite clear it could never be available more than as an auxiliary to the knife, by which alone the various channels of a complicated fistula can be traced.

Dr. Benson observed that Dr. Colvan was well known to and much respected by many of the members present. He (Dr. Benson) was not disposed to say much in favour of the ligature, though he was of opinion that in many cases occurring in very timid patients it might be prefered to the bistoury. Perhaps Pott's condemnation of the ligature was too sweeping when he said, "It would be an abuse of the reader's patience to dwell on it, as the operation is, on every principle of ease, expedition, safety, and certainty, unfit for practice." Press of business, Dr. Benson feared, would preclude the discussion of the merits of the operation on that night.

Two new instruments, the one a uvulatome, the other for dividing the frænum linguæ, were produced.

Dr. Beatty, in bringing these instruments before the Society, said he would not occupy their time at any length, as he and the other members looked forward with much pleasure to hearing the address about to be delivered by the learned President at the close of the evening. Dr. Beatty then alluded to the difficulty and danger frequently attendant on the performance even of the trivial operation of division of the frænum linguæ in children; the difficulty consisting in the elevation of the tongue by means of a finger placed beneath it—a proceeding in some instances impossible when (as happened in a child on whom Dr. Beatty had lately operated with the new instrument) the whole body of the tongue, even to its tip, is tied down to the floor of the mouth. Impressed with the necessity of obtaining some contrivance by which a division of the vessels at the root of the tongue might be avoided, Dr. Beatty gave the subject some attention, and had constructed the instrument now exhibited, which resembles very closely the ordinary dressing scissors, its blades, however, being perfectly blunt and curved, and not closing completely, an interval being thus left which receives the frænum. The instrument enables the operator to elevate the tongue and stretch the frænum, and so to avoid wounding the sublingual vessels.

The next instrument—the uvulatome—Dr. Beatty observed, displayed much greater ingenuity in its construction, and was the production of Dr. Carte, who, to have its merits accurately represented, ought himself to have submitted it for the inspection of the Society. It had been placed in his (Dr. Beatty's) hands by Mr. Millikin, by whom it had been constructed, and he looked upon it as an exceedingly ingenious contrivance for facilitating the removal of a portion of the uvula; for this, though a very simple operation, is sometimes attended with difficulty, and occasionally, too, with danger, on account of the detached portion falling into or against the air passages. The instrument consists essentially of a pair of scissors with blunt points, but, in addition to the ordinary cutting blades, there are beneath these, attached by means of screws, a pair of blunt supplementary blades, whose flat surfaces come in contact with the uvula and seize it while it is being detached by the cutting blades, thus constituting an effectual provision against the occurrences just alluded to.

Deafness from various Causes.

Dr. R. J. Massy, who has devoted a good deal of attention to aural surgery and the diseased conditions of the membrana tympani by investigation through means of the auriscope constructed by Dr. Warden, of Edinburgh, read two or three cases to the Society, the most remarkable of which arose from scrofulous deposition in the membrana tympani.

The President's Address.

The President first proceeded to read over the proceedings of the Society during the past session, occasionally commenting on the communications of most interest, of which, as they have all been already before our readers, it is only necessary to remark that many of them were mentioned by the President in terms most flattering to the contributors.

"Never," continued Mr. Carmichael, "having attended the meetings of the Society as President of the College until this year, I had a very inadequate notion of the depth and extent of information to be obtained not only from your written transactions, but from the research, clash of intellect, and astuteness of mind which the discussions upon each subject brought out; and permit me also to express the pleasure I experienced in observing, that, however different and opposite the views on the subject under discussion might be amongst you, the debates were conducted in a spirit of the most perfect amenity, good feeling, and gentlemanlike demeanour, evincing that the great object in view was the ascertainment of truth.

"The construction or arrangement of this Society is excellent; for while those alone qualified to practise the medical profession join in debate, the juniors on the cross-benches, although silent, are not

debarred from the information to be gathered at your meetings.

"Gentlemen, while listening with pleasure and advantage to your communications and discussions, I could not but feel deep regret that the public were not sufficiently aware of the acquirements and practical information of the regularly educated medical men of this city; and that, instead of placing their confidence entirely upon them, they should so frequently bestow it upon others in every respect their inferiors. But I have no doubt that ere long the intelligent portion of society will perceive the folly and absurdity of trusting their health and lives to those who are in no way qualified for so important a trust.

"The medical profession in Great Britain is at present most peculiarly and unhappily circumstanced. It has been for centuries, as in the rest of Europe, divided into three classes:—Physicians, surgeons, and apothecaries.

"With respect to physic and surgery, it is now universally admitted to be an artificial division not existing in nature; and between which—excepting surgical operations—no distinct line of demarcation can be drawn, and, therefore, it is now granted that any individual, to practise either branch as he ought, should be educated in both.

"But it is quite the reverse with respect to pharmacy. An apothecary can perform the duties of his department, though totally ignorant of the structure and functions of the human frame, either in health or disease. Indeed, it would be better that he was totally ignorant on those points, as such knowledge might lead him away from attention to his own peculiar vocation.

"Yet, strange to say, the apothecary in civilised England, and in Ireland of late, is engaged much more in the business of prescribing than of compounding medicine. So much so is this the case, that at least three-fourths of his time is occupied in the pursuit of medical practice, while his shop is left to the care of his apprentices and assistants.

"Now, it is self-evident that while he is thus engaged in the pursuit of medical and surgical practice, supposing him even qualified for the duty, he must of necessity neglect his legitimate business—the preparation and compounding of medicines; and it is equally self-evident that an apothecary's shop is not the fitting place to learn anatomy, physiology, and the nature and treatment of diseases. Therefore, while he neglects his own peculiar department, he occupies a position he is unfitted to hold, to the exclusion of those who have *laboured for years, hard and assiduously, to qualify themselves for trusts the most important.*"

The President went further into detail respecting the evils connected with the association of the practice of pharmacy with that of medicine and surgery, and concluded a long and eloquent address with the following observations:—

"If Sir James Graham had thrown overboard the selfish representations of medical corporations, and only attended to a very few principles upon which medical reform, to be useful to the nation ought to be based, he would not have been foiled in his benevolent and patriotic exertions.

"These principles are:—

"1. An improved system of education, both preliminary and professional.

"2. The union of physic and surgery, at least in education.

"3. The separation of the practice of pharmacy from that of physic and surgery.

"Lastly. Uniformity of qualification, as far as can be obtained, and reciprocity of privileges to the profession in each great division of the United Kingdom."

The President dwelt upon the great advantages that might be expected to arise to the profession and the public from a legislative system founded upon these few but important principles, and said, in conclusion:—

"Gentlemen, I ought to apologise perhaps for introducing a subject that many may esteem foreign to the objects of this Society, but it arose naturally from the indignation I feel at seeing those heretofore subordinate to our profession interfering thus with the legitimate rights of such men as I see before me—men who, after a severe and protracted course of study to learn a complicated and most difficult profession, are immensely neglected by the public, although as highly informed in all its branches and as well prepared to meet the wants of the community as can be met with in the metropolis of England or in any part of the world."

PATHOLOGICAL SOCIETY OF DUBLIN.

Meeting of the 28th March, 1846.

[From our own Correspondent.]

DR. O'FERRALL in the Chair.

Endocarditis of Five Days' standing.

Dr. Corrigan said the preparation before the Society was one not of very common occurrence, and as it was likely to afford some instruction, he thought it worth presenting. The preparation was illustrative of the results of endocarditis of only five days' standing, the valves being free from organic disease. There is yet, he remarked, insufficient information as regards the pathological conditions attributable to the first stage of endocarditis, and in the heart which he now exhibited was seen at this early stage the deposition of lymph, which leads to the subsequent process of contraction that closes the auriculo-ventricular orifice. The subject of this case, a girl named Hyland, aged eleven, had an attack of scarlatina, from which she became convalescent on the 17th of this month, and the day after was attacked with the ordinary symptoms of pericarditis, dyspnœa, cough, pain in the cardiac and epigastric regions, and tenderness in the latter when pressed hard. The pulse was 125, and the action of the heart tumultuous, together with indistinct bruit. Next day the symptoms were aggravated, the dyspnœa became more urgent, the pulse 130, and the bruit now loud. No friction sound existed over the heart, but there was extensive dulness on percussion over the cardiac region, extending as high as the left sterno-clavicular articulation, and beyond the right border of the sternum into the right side. Under this continued aggravation of the symptoms, the pulse remaining at 130, but now becoming almost imperceptible, and the other symptoms as he had sketched them, the patient died on the night of the fifth day from the commencement of the attack.

A diagnosis of pericarditis and endocarditis had been made, and upon examination the pericardium was found distended with fluid to the amount of a pint or more, and it extended laterally so far as a couple of inches beyond the right border of the sternum, not by dragging the diaphragm in that direction, but from actual distension of the bag itself. It extended also as high up as the left sterno-clavicular articulation, and downwards beneath the mamma of the right side.

The specimen so far, Dr. Corrigan observed, presented nothing with which the Society was not already familiar; but he now came to the point of interest connected with it. When the heart was opened, a deposition of rough lymph of considerable thickness was seen along the whole of the free edge of the mitral valve, so exceedingly well marked that when first seen he knew of nothing to which it might more aptly be compared than a thick cord of light red chenille stitched along the edge of the valve. This rough deposition of lymph, he observed, is exactly analogous to that which is observed in peritonitis, or serous inflammation in any other part of the body.

Examined through a magnifying glass of very low power, this edging of lymph is seen as a soft, pulpy, irregular bordering, running all round the valve. With a little force it can be torn off, leaving the serous membrane of the edge of the valve unaltered beneath.

It can be now readily understood how this deposition would ultimately cause narrowing. The lymph would soon become fully organised, and then, taking on the process of contraction, which lymph under such circumstances always does, the final result would be the circular contraction of the fore edge of the valve, and at least the ordinary appearance of narrowed auriculo-ventricular opening. The situations in which the lymph had been deposited also explain the circumstance observed in confirmed narrowed auriculo-ventricular opening, viz., that the free or floating edge of the mitral valve is the seat of the contraction, while the middle portion and base of the valve attached to the annular tendinous margin remain unaffected.

Dr. Clarke presented to the Society a specimen of aneurism of the abdominal aorta, taken from the body of a man lately under the care of Dr. Ferguson at Sir P. Dun's Hospital; through the kindness of that gentleman he had an opportunity of presenting it to the attention of the Society.

The man was thirty-five years of age; a clarionet player by employment; of intemperate habits, but never had suffered from any affection of sufficient importance to confine him to bed, with the exception of an accident he met with about two and a-half years ago, namely, falling from a car while in a state of intoxication, and which occasioned a fracture of the seventh and eighth ribs of the left side, a little external to their angles. From this he recovered perfectly, and was able to pursue his old habits until last October, but now began to suffer from dull pain in the scrobiculus cordis, lost his appetite, rest, &c., and became much emaciated.

He applied for relief at a dispensary, where he was told he had disease of the kidneys, and continued his attendance there, without benefit, up to the period of his admission into the hospital, which occurred on the 3rd of March, 1846, the symptoms being then as follow:—Countenance expressive of great distress and apprehension; very considerable emaciation; colour anæmic; complained of a dull heavy pain in the epigastrium, always worse after eating, whether much or little, and the aggravation of suffering lasting for about half an hour after meals, then moderating to its regular intensity, the spot over which the pain was felt not being larger than the palm of the hand. He also complained of lancinating pains along the posterior edges of the borders of the ribs, corresponding with the insertions of the diaphragm. He asserted positively that both these pains were constant, never remitting; there was some slight dysphagia; and the patient lay easiest in a position midway between the lateral and supine, his pelvis being flat, while his neck and shoulders were bent towards the left side, one leg being flexed on the trunk, the other extended. He suffered from palpitation of the heart; total want of rest; pulse 112, and small; appetite bad; bowels usually confined; the urine, he said, did not run in its usual free way, though he was obliged to pass it more frequently than natural; this Dr. Clarke supposed gave rise to the man's having been pronounced to be affected with renal disease.

On examination of the epigastric region, a tumour, the size of a small orange, was distinguishable, midway between the umbilicus and ensiform cartilage and to the left of the mesial line, which pulsated strongly. On applying the stethoscope, a loud bruit, synchronous with the impulse, was audible, but on tracing the aorta downwards to the umbilicus, both impulse and bruit were lost; and on passing upwards towards the heart, the bruit gradually diminished in intensity, until over the heart it was lost altogether. The sounds of the heart, further than being weak, presented nothing unusual.

On pursuing the examination posteriorly, a very obscure impulse was obvious on either side of the spine, unattended with any bruit. Whether this latter was owing to the greater thickness of the superimposed parts, as compared with the anterior wall of the abdomen, and thus preventing the communication of the sound, or that the erect position of the patient while being examined posteriorly caused the blood to gravitate more directly on the tumour, distending its walls, and thus preventing the bruit, Dr. Clarke was unable to say, as he had neglected to examine him anteriorly in the erect position, which of course would at once have shown the presence or absence of bruit as determined by position. The chest offered nothing in its auscultatory phenomena, further than extreme weakness of respiration.

The diagnosis was aneurism of the aorta above the cœliac axis, probably arising from the anterior wall of the artery, from the absence of all neuralgic symptoms affecting the testis, bladder, sciatic, or crural nerves. With respect to treatment little need be said; it consisted of that generally adopted in such cases, viz., restriction as to fluids, small quantities of animal food, very small bleedings

narcotics, locally and generally. The only difference noticed from the time of admission was a return of appetite, and a considerable relief at first from the use of opiates, but on the sixth morning after admission he complained of extreme pain, and there was great restlessness; the pulse hemorrhagic, and considerable tenderness of the epigastrium, in which state he remained until one o'clock the usual hour for patients to be visited by their friends; at this time his sister came to see him, and he expressed himself immediately relieved from pain, and remained conversing with her until the hour had elapsed. She had hardly left the ward when he was seized with vertigo, tinnitus, and faintings. He remained insensible for some minutes, and then was roused by gentle stimulants. At four, p. m., he had a similar attack, from which he was also roused, but it was almost immediately followed by a third and fatal fainting fit.

On examination of the body eighteen hours after death, there was observed, externally, considerable emaciation with extreme rigidity of the muscles. On opening the cavity of the abdomen, a small clot of blood, not more than four ounces, was found smeared over the surface of the small intestines. This proceeded from the great omentum, the layers of which at their attachment to the stomach were separated by a large clot of blood, which had passed down behind the stomach under its peritoneal coat from the lesser omentum, the cellular tissue of which was also distended with coagulated blood. On removing the aorta, œsophagus, stomach, and intestines, the aneurism was found to arise, as had been supposed, from the anterior wall of the artery by an oval opening, about half an inch long, and just corresponding to that part of the artery which passes behind the crura of the diaphragm. The diaphragm was inseparably connected to the cyst of the aneurism. On the left side the opening in the cyst was extremely small and to the inner and right sides of the œsophagus. From this the blood had been effused into the layers of the lesser omentum, and had passed upwards along the œsophagus towards the posterior mediastinum. The heart was found very slightly dilated without hypertrophy, the valves somewhat thickened, not to a degree, however, to interfere with their function; the arteria innominata was much thickened and cartilaginous.

MISCELLANEOUS CORRESPONDENCE.

HICKMAN *VERSUS* DICKENSON.

[To the Editor of the Medical Times.]

SIR,—You may have more influential, though perhaps not many stauncher supporters than myself. I advocate your cause, because I have observed that while your pages are open to all that is interesting to the profession, they are closed against those paltry effusions which seek to injure the character of a professional brother by wantonly laying bare some unfortunate mishap which may have befallen him in his practice. In common with others who read an account of the trial for manslaughter of Mr. Dickenson, I cordially concurred in the disgust evidently felt by the judge at seeing such a case brought into a criminal court. Consider it in its worst light: allow that in a moment of agitation Mr. Dickenson mistook a clot of blood for the placenta. Would it not, I ask, be the duty of a brother practitioner, on finding out the error, at the same time that he took the necessary steps to remedy the mischief, to do all in his power to keep the bystanders from discovering the mistake? Is it the usual custom of respectable medical men on such occasions to call out, "Do you call this the after-birth? I will show you the after-birth." (Medical Times, p. 514.) Where is the medical man who has been in practice for any length of time who could truly affirm that he has never made an error in judgment which has endangered the well-doing of his patient? I believe such a one is not to be found, and the regret that this liability to error is universal, ought to make all proper feeling practitioners tender of the reputation of others. The man who would maliciously take advantage of a mistake to ruin another's practice ought to be looked on as a foul blot on his profession. I should never have addressed you thus, only I grieved to see your pages taken up with such a letter as that of Medico-Chirurgus. Peruse it carefully, and see whether you think its *ostensible* object—the benefit of the junior members of the profession—is likely to be accomplished. The animus which dictated it is far too glaring to admit of such a supposition. If such conduct as that of the promoters of this trial is to be held up to admiration instead of reprobation, in vain may the National, or any other Association, strive to improve the standing in society of the general practitioner.

I trust, Sir, that in your next number you will notice this subject, and I hope that the insertion of the letter may have been an oversight. On first reading it I was forcibly reminded of days gone by, when a journal which then occupied your present eminence, with merciless venom, not only watched with the eyes of Argus for an unfortunate case in order to damage the reputation of any one who was not a sworn supporter; but allowed quiet and peaceable practitioners, to be at any moment dragged before the public by the waspish malevolence of some mean spirited rival. It would not be uninstructive to calculate the share that this has had in bringing the said journal into its present unsaleable condition.

I am Sir, your obedient servant,

MEDICUS.

⁂ On the principle of hearing both sides, we give insertion to this note. The letter it replies to was furnished us by an able correspondent, who gave us his name. We published it as a comment on a *public trial*. We agree with Medicus on the cruelty of making a professional mistake in private practice the source of further suffering to its unfortunate cause; but public investigations before the country's judges stand in a somewhat different position. Here must end the correspondence.—ED.

POISONING IN NORFOLK.

An investigation took place at Happsburg, in Norfolk, on Monday evening last, before the coroner Mr. Pilgrim, of which the following are the principal facts:—The village of Happsburg is situate on a cliff overhanging the sea, thirty miles from Yarmouth, and fifteen miles south of Cromer, and is better known as Haisborough, from its contiguity to the famous light-house of that name. It is one of the most secluded villages along the coast, with a population of two or three hundred In. the parish, Jonathan and Anne Elizabeth Balls, the former seventy-seven, and the latter eighty-three, were supported by parochial relief. They had three daughters married, who had a number of children; several of these having died suddenly, the coroner's inquiry arose. Three years ago an infant nine weeks old, named Anne Elizabeth Pestle, a grandchild of Balls, died, and was buried in Haisborough churchyard within a few hours. The next was a boy, Samuel, of the same parents, whose death took place under precisely similar circumstances in last September, and was interred by the side of his sister. Three months afterwards two more deaths in the family occurred—the wife of Balls, and another of the grandchildren, Elizabeth Anne Pestle, who were both buried on one day. No suspicious feeling seemed to exist. However, the death of Balls, occurring on the 20th ult., after being attacked in a similar way to the other deceased members of the family, many rumours got afloat in the neighbourhood that his death, with the others, had been the result of poison. The corpse was buried, and a large number of villagers attended the funeral. Not the slightest notice was forwarded to the coroner by the parochial authorities, but numerous communications were sent to the coroner, and that gentleman at length issued a summons to the authorities for the disinterment of Jonathan Balls and Anne Elizabeth Pestle, the little girl, who were buried on the same day, and empanelled a jury to inquire into the cause of their deaths. At the first meeting of the jury, the coroner, in consequence of some private information he had received, to the effect that the deceased's death had really taken place from poison, the extraordinary preservation of both bodies indicating the fact, refused to swear Anne Pestle, a decent-looking woman, the mother of the child, who it was understood was the only witness that could throw any light upon the affair. This course, it appears, was adopted from the circumstance of her having some twelve years ago bought arsenic for the purpose of destroying rats. Being desirous of affording all the information she could, she stated that her child had certainly died suddenly, as well as her father, but she had not the slightest reason to suppose that they had died from poison. The death of her child she attributed to sore throat, and her father's to old age. The jury, on viewing the remains of Balls, were surprised on finding in the coffin two walking sticks, one on each side of the body, an iron poker, several pocket handkerchiefs, and a piece of plum-cake in each hand. The inquest was adjourned in order to allow of a *post mortem* examination being made, the coroner again adjourned the inquiry until Monday last, with a view of having the three other bodies lying in the church-yard exhumed and examined, as the medical gentleman had satisfactorily ascertained that the death of Jonathan Balls and his grandchild Anne Elizabeth Pestle had been produced by arsenic.

The following witnesses were examined:—

William Pestle, a labouring man, son-in-law to the diseased, Jonathan Balls, identified the bodies as those of Elizabeth Balls and Anne Elizabeth and Samuel Pestle. His mother had been dead nineteen weeks. He saw her a few hours before she died. She appeared to be very quiet, as if asleep. No surgeon attended her, and she had been bedridden for the last four years. There were in the house at the time of her death, his wife, Mary Green, and Elizabeth Peggs, married women; her daughter, Mary Slaughter; Sarah Kerrison, the servant; and old Jonathan Balls. He did not know anything about the poison they were said to have had. He did not know anything about poison being purchased by his wife. He had heard her say that, thirteen or fourteen years ago, she wrote a note for arsenic, and sent it with a little girl for the purpose of killing the rats. His master, Mr. Pye, suggested that poison; but he never saw any of it in the house. It was laid for rats in the coal-house. Never heard of any poison being purchased just before Mr. Ball's death. The first time he heard anything of it was yesterday fortnight. He was told of it by John Wright about a week after Jonathan Ball's death. He told him that he had been to Mr. Heckley's, a druggist of Statham, and purchased some arsenic to kill rats.

Sarah Kerrison, a young girl living as servant at Great Yarmouth, lived with Mrs. Balls for near five years, until she died. She attended to her. Her husband was much with her. Mr. Clowes attended her occasionally. On the Friday previous to her death she was taken very sick. She was very feeble. She could not attend upon herself. Had seen her husband give her some drink, generally cold water or cold tea. He always mixed the tea for her. She used to drink it from the spout of the tea-pot.

Coroner.—Did you ever notice anything unusual in his making the tea?

Witness.—One day after she was taken seriously ill, I saw Balls, her husband, put some water into the teapot, and then drop two or three pinches of a powder into it. It was white, and seemed to be flour; did not know where he got it from; thought at the time he was putting in something to do her good. This took place on the Saturday, and she died on the Tuesday. She was very sick afterwards. The daughters did but very little for her; they did not understand her ways. She was very fond of them, and they of her. The old man seemed very kind to her. Never knew of poison being kept in the house. I was taken ill on the Saturday night previous to the wife's death; I was very sick, and he said to me, "I suppose we are all going to be taken alike."

By the Coroner.—One of the daughters was taken ill—Mrs. Green; she had eaten a piece of herring for breakfast on the Saturday morning, and she thought it made her ill; cannot recollect what I had been eating. Mrs. Green and I were sick together. Old Mr. Balls was sitting at the table. I drank tea with them. Cannot say who cooked the herring. I was taken ill after breakfast. I am sure that the white stuff was not tea. He put it in quickly, as if he was desirous of no person

seeing what he was about. Did not notice an sediment at the bottom of the water in th pot.

Phœbe Anne Neave, a single woman, said—have known Balls some years. About two years ago he asked me to write a letter to Mr. Sadler, o North Walsham, druggist, to get some arsenic, he had rats, or he wanted to destroy rats. refused several times, and said, "I must not do it, as I have heard of many bad things being done witl it." He replied, "You need not be afraid, I am not going to use it for any bad purpose;" but stil refusing, he remarked, "Why can't you write on for me as well as for my daughter, Mrs. Pestle?" I told him I was then young, and knew no better, as it was twelve years ago.

Mary Slaughter, residing in the same house as Mrs. Pestle, deposed—I knew Balls, his wife, and grandchildren, and attended them when ill. recollect that the whole of them were sick a few hours before they died. The little girl, Anne Elizabeth Pestle, who was nine weeks old, died first. She had been ailing and was wasted away. She died in my arms. The grandfather came frequently to the house after she was dead, and said it was a happy release. Samuel was the next that was taken sick. He was taken ill at the grandfather's, who brought him home to his father's. He was taken ill about five o'clock in the evening, and died at eight o'clock the same night.

By the Coroner.—We thought the children might have died from sore throats. Never saw children die in such a way as Mrs. Pestle's. Believed a child of Mrs. Green's died some years ago at East Reston, after visiting the deceased Balls, in rather a sudden manner, and a coroner's inquest was held upon it. A post-mortem examination was not made.

Mr. G. W. Firth, surgeon, of Norwich, was then examined.—I assisted Mr. Clowes in the post-mortem examination of the bodies that have been exhumed this day. We first examined the infant; it was so much decomposed that its various parts could not be distinguished, and therefore, though we have been unable to trace poison, it is possible that it may contain some. We have looked for arsenic, and have applied the usual tests, and a more elaborate and prolonged examination might detect it. We next examined the boy, Samuel Pestle. The internal organs were in a remarkabl state of preservation. We found some small ulcer in the stomach, which was coated with a brillian yellow matter. These yellow appearances we sus pected were a decomposition of the white arsenic We cut out one of these yellow spots, and succeede in reducing the metallic arsenic from it, and applie other tests, which proved beyond all doubt the existence of arsenic. We conclude, therefore, tha it caused death. We then examined the ol woman. The stomach was quite empty. We examined some of the coating of the stomach and a proportion of the liver. In each we found distinct traces of arsenic. Finding arsenic in the liver leads to the supposition that it must have been taken in a large quantity. I have no doubt about it.

Mr. R. Clowes, surgeon of Statham, after fully corroborating the testimony of Mr. Firth, said—I attended Balls a few hours previous to his death He was purging and vomiting, and complained of pain about his stomach. I only suspected at the time that he had taken some improper diet. The son-in-law informed me the next morning that he was dead. I did not at the time suspect he had come to his death by unfair means. On Monday last, after his body had been exhumed, I made a post-mortem examination, removed the stomach, and carried it home. I subjected a portion of the stomach to a chemical analysis, and found it contained a large portion of arsenic, which was undoubtedly the cause of death. I also examined the stomach of Anne Elizabeth Pestle, the little girl, and the appearances were similar to those of Balls, There was arsenic found in the stomach quite sufficient to cause death.

The three daughters of Balls—Mrs. Pestle, Mrs. Green, and Mrs. Peggs—were then called in by the coroner, who observed that he did not know what turn the case would have taken, and therefore he thought it best not to examine them on oath. He had called them in to give them an opportunity o making any statement they might desire.

They expressed every willingness to further th investigation, and Mrs. Pestle reiterated her forme statement. She was sure the arsenic which sh purchased some years ago was destroyed. Th sticks, cake, poker, and playthings of the little gi were put into her father's coffin, according to hi urgent request.

Mrs. Green, one of the daughters, also made statement, and the officer of the court announcing that he had no further witnesses, the coroner proceeded to sum up the evidence. He thought th facts did not fix upon any party so as to warran them in sending the case to another tribunal. I any one was inculpated, the finger of suspicion most certainly pointed to the deceased Jonathan Balls, and he was beyond the reach of the law. He recommended them to return such a verdict as would enable the officers to have the matter further inquired into, should such circumstances arise as required it.

The jury then found, after half an hour's consultation, "That the deceased, Jonathan Balls, Elizabeth Balls, Samuel Pestle, and Anne Elizabeth Pestle, died from the effects of poison, but how administered there was no evidence to show."

A SELECT PRACTICAL FORMULARY.

Translated from the French of M. Foy, Principal Pharmacien to the Hospital Saint Louis, at Paris.

TAFFETAS OF ENGLAND (Court Plaister).—A solution of isinglass in alcohol, spread upon rose or black taffetas, and aromatised with the tincture of the balsam of Peru.

TAFFETAS, BLISTERING (Codex).—Four parts of oil of cantharides obtained by ether, eight parts of yellow wax, mixed together by means of a gentle heat, and spread on linen or waxed taffetas.

TAKAOLI, TAKALI, OR TAGALI.—Extracts bearing one of these names are found in some druggists' shops. They are proposed as succedanea for the extract of bark.
